*"To the solid ground
Of Nature trusts the mind which builds for aye."*—Wordsworth.

THURSDAY, MAY 3, 1888.

VOLAPÜK, PASILINGUA, SPELIN, LINGUALUMINA.

Volapük or Universal Language. By Alfred Kirchhoff. (London: Swan Sonnenschein and Co., 1888.)

Key to the Volapük Grammar. By Alfred Kirchhoff. (London: Swan Sonnenschein and Co., 1888.)

Elementar Grammatik zur Weltsprache (Pasilingua). By P. Steiner. (Berlin: Louis Heuser, 1887.)

Spelin, Eine Allsprache. By G. Bauer. (Agram: Franz Suppan, 1888.)

Lingualumina, or Language of Light. By F. W. Dyer. (London: Industrial Press, 1875.)

"IF only we had been consulted at the creation of the world, good as the general working of the machine is, how many little improvements might have been introduced!" This remark, not meant to be irreverent, is often heard when people suffer from toothache either at the arrival or at the departure of their molars, or when a sudden frost sets in and destroys the blossoms on all the fruit-trees in their garden. Volapük seems suggested by the same kind of sentiment. Languages, the adherents of Volapük seem to say, are all wonderful machines, but, if we could only have been consulted by the original framers of human speech, how many little irregularities might have been eliminated, how much might the whole working of the machine have been simplified, and what a saving of fuel might have been effected if instead of a thousand of these linguistic machines, each having its own gauge, there had been one engine only, taking us from Fireland to Iceland without any change of carriages.

Those who lament the imperfections of human speech may claim, however, this advantage over the grumblers at the world at large, that they are quite prepared to produce a better article. Again and again has the world been presented, not only with new alphabets and new systems of spelling, but with brand-new languages. Of late, however, there has been quite a good measure of them pressed down and running over. At the head of our article we have mentioned four only, called respectively *Volapük*, *Spelin*, *Pasilingua*, and *Lingualumina*. But there have been several more proposals for a universal language sent to us lately from various quarters of the world, all equally ingenious, though we are sorry we cannot disinter them from beneath that mighty cairn of pamphlets which is growing up from week to week in our library.

All these proposals have one thing in common. They start from a fact which cannot be disputed, that life is too short to learn more than four or five languages well, and that it is perfectly wicked to write books on scientific subjects in any language but English, French, German, or Latin. They then go off into raptures about the days when "the whole earth was of one language and one speech," and they even appeal to prophecy that it has been promised "that a pure language will be turned to the people, that they may all call upon the name of the Lord, to serve him with *one* consent."

And how is that prophecy to be fulfilled? Here the answers begin to vary a little. Some people say, Let everyone learn English, and the problem is solved at once. So it would be, so perhaps it will be, when the leopard shall lie down with the kid. But till that comes to pass different kinds of compromise are suggested. First of all, as to grammar, there is no excuse for any irregular nouns or irregular verbs, for gender as different from sex, for obsolete degrees of comparison, or for any involved syntactical constructions. These ought all to be abolished. Secondly, as to the dictionary, it is quite clear that if 15,000 words sufficed for Shakespeare, a dictionary of 250,000, like the English dictionary now being published by the University of Oxford, is the most fearful extravagance ever known. Here all inventors of a new language insist on retrenchment. The inventor of Volapük was satisfied at first with a dictionary of 10,000 words, but we are now promised a new one of 20,000.

There is a great difference of opinion, however, when the question arises from what source these words ought to be derived. Some draw their words at random from a number of the best-known languages, others confine themselves, as much as possible, to words common to German, French, and English. *Volapük* draws on several banks, chiefly on English, but it clips its coins fearfully. Thus, its very name, *Volapük*, is taken from German and English. *Vol* represents the German *Volk*, *pük* the English speech, so that *vola-pük* means originally folk-speech. In the same manner *appetite* has been replaced by *potit*, *abundance* by *bundan*, *silver* by *silef*, *Jew* by *yudel*, *house* by *dom*. In many cases these borrowed words have been so much changed that it is difficult to recognize them. Here *Pasilingua* has a great advantage. All its words remind us of a Teutonic or Romanic prototype, or of English, which has amalgamated these two elements in its dictionary. Volapük often requires a commentary, where Pasilingua allows us to guess with a good chance of success. Thus—

What o'clock is it? is in Volapük *Düp kimid binos?* in Pasilingua *Quota hora er al?*

Where do you live? is in Volapük *Kiplace lödens?* in Pasilingua *Ubi habitirs tüs?*

The sentence, Advertisements are to the man of business what steam is to industry, has been rendered in Volapük by *Lenunc binoms jafaman otos kelos stemplo dustor*; in Pasilingua by *Annóncius ers pro tos affäriros qua ta vapora pro ta industriu.*

After Volapük has once chosen what may be called its stems, which consist mostly of a consonant, a vowel, and a consonant only, everything else becomes easy enough Thus if *fat* stands for father, we get a simple declension:—

	Singular.	Plural.
N.	*fat*, father	*fats*
G.	*fata*	*fatas*
D.	*fate*	*fates*
A.	*fati*	*fatis*

Pasilingua declines:—

	Singular.	Plural.
N.	*mortu*, the death	*mortas*
G.	*mortude*	*mortasde*
D.	*mortuby*	*mortasby*
A.	*mortun*	*mortan*

Spelin declines:—

	Singular.	Plural.
N.	*mik*, a friend	*mikoes*
G.	*doe mik*	*doe mikoes*
D.	*tu mik*	*tu mikoes*
A.	*mik*	*mikoes*

It is clear that there are ever so many ways by which the same result might be obtained, so long as the principle is strictly adhered to that each case shall have but one sign, and that the same sign is to be used in the plural and the singular, while the plural again is indicated by a sign of its own. In Bengali and many other languages the same principle is carried out with considerable consistency. What applies to declension applies to conjugation, to degrees of comparison, and to derivation. All becomes regular, simple, intelligible, whatever set of suffixes, prefixes, or infixes we adopt. Thus, to have is *lab* in Volapük. Hence:—

Singular.	Plural.
labob, I have	*labobs*, we have
labol, thou hast	*labols*, you have
labom, he has	*laboms*, they have
labof, she has	
labos, it has	
labon, one has	

By assigning to each suffix one peculiar power, Pasilingua distinguishes: *mortu*, death, *morto*, dead, *morte*, dead (fem.), *morta*, dead (neut.), *mortiro*, dying, *mortaro*, murderer, *mortamenta*, instrument of murder, *mortana*, poison, *mortarea*, battle-field, *mortitarea*, churchyard, *mortiblo*, mortal, *mortablo*, fatal, *mortoblo*, easy to kill, *morter*, to be dead, *mortir*, to die, *mortar*, to kill, *mortor*, to be killed, &c.

These few extracts will give our readers an idea of what they have to expect from *Volapük*, *Pasilingua*, and *Spelin*. *Spelin* has nothing to do with spelling. It is derived from *lin*, the abbreviated stem of *lingua*. *Pe* (from Greek *pas*) means all, *s* on account of its continuous buzzing sound is used to form collective nouns; hence *s-pe-lin* means all-language, or *Pasilingua*.

The study of these systems is by no means without interest and advantage. It will help to clear people's ideas about the great complexity of language, and show how simple a process grammar really is. If more generally adopted, as Volapük seems likely to be, such a system of writing may become even practically useful, particularly for telegraphic communication. That it could ever supplant our spoken language is out of the question, and Dr. Schleyer, the inventor of Volapük, distinctly disclaims any such intention ("Hauptgedanken," p. 10, note). One protest only we have to enter before leaving the subject. Nothing could be a greater mistake than to imagine that these clever and amusing experiments have anything in common with Leibniz's conception of a philosophical language. What Leibniz had in his mind may be guessed from the "Essay towards a Real Character and a Philosophical Language," by Bishop Wilkins, London, 1668, of which an abstract is given in Max Müller's "Lectures on the Science of Language" (vol. ii. p. 50). This is as different from Volapük as the *Kriegspiel* is from real warfare. For spending a dreary afternoon pleasantly, an experimental study of *Volapük*, *Pasilingua*, or *Spelin*, may safely be recommended. *Lingualumina* is a more serious matter. It is built on an exhaustive analysis of the notions that have to be expressed, and thus approaches nearer to the ideal which Leibniz had conceived of a perfect and universal language.

BRIDGE CONSTRUCTION.

A Practical Treatise on Bridge Construction: being a Text-book on the Design and Construction of Bridges in Iron and Steel. For the Use of Students, Draughtsmen, and Engineers. By T. Claxton Fidler, M.Inst. C.E. (London: Charles Griffin and Co., 1887.)

THIS book is principally intended for practical use by engineers and draughtsmen, who are now being called upon to design and construct bridges of unprecedented magnitude, like the Forth Bridge, which the introduction of iron, and latterly more especially of steel, has rendered possible. The execution of these requirements has brought forward a number of new problems to be solved in Statics, and the Elasticity and Strength of Materials, and has invested old problems with an importance which they did not before possess. Evolution in this branch of creation has gone on so rapidly that the Darwinian student of the "survival of the fittest" might turn to this book for striking exemplifications of his theories, which he would find in the classification of bridges, described and illustrated in the second section of the work. But while in the animate kingdom the mammoth animals have become extinct from insufficient mobility and relative strength to carry their own weight, the converse operation is observable in engineering construction. Bone and muscle are of the same strength as formerly, but the improved manufacture of steel has placed in the hands of the engineer a material with which he can safely attempt his mammoth creations; and should metallurgical science provide commercially for the engineer a new metal, as strong as, or stronger than, steel, but of less weight—say, aluminium—then we may expect to see still more marvellous developments in bridge building.

The bridge, on a large scale, resembles the mammoth or giant in requiring its whole strength to keep itself upright; and one of the most interesting theoretical questions discussed in the present treatise is the consideration of the maximum span possible with the material in hand—say, steel. When the span is large, the greatest economy in details must be practised, as the chief stress is due to the dead weight of the bridge, and not to the relatively insignificant weight of the moving load. Thus in the Forth Bridge a weight of 20,000 tons of steel is required in a single span to provide it with the necessary strength to hold itself up, so that the stresses due to a train of 200 tons running across may be left out of account.

The weight of metal worked into a bridge is at once a measure of the stresses in the material, and also of the quantity, and consequently the cost, of the materi al used. The author employs the customary units of engineers, the pound or ton as a measure of force and of weigh, and measures stresses in pounds or tons per square inch. He does not find it necessary to express his stresses in poundals per square foot, nor does he measure quantity of material in units of mass, which are *g* pounds or tons, as we are taught in theoretical text-books.

The mathematical student, to whom the book is partially addressed, will find it, while valuable as a handbook for a practical engineer, at the same time stimulating to his imagination in the realms of pure Abstract Mechanics, which at present run the risk of wandering away from reality, because the writers of modern text-books of mathematics do not look to the wonderful creations of modern engineering science for illustrations of theory. Thus the methods of Graphic Statics, largely employed in this treatise, arose out of the requirements of an engineer's office: a draughtsman was found using the method, and Prof. Maxwell seized upon it and elevated it to the rank of a new method in Mechanics.

Scientific treatises on Practical Mechanics are more common in America, where the requirements of opening up a vast continent have given great employment to the engineer and the bridge-builder; and it must be owned that these treatises are far superior to our own. But we hope the present treatise will do something to take away this reproach.

We may flatter ourselves that the Forth Bridge now in progress is the greatest thing of the kind in the world, but a rival in the Poughkeepsie Bridge is projected. These two bridges will exemplify the difference of practice of the Old World and the New. In our practice the whole bridge is riveted up into a rigid structure as much as possible; while in America the articulated system of triangular cells, with pin joints permitting rotation, is adopted, the stress in individual members being thus a simple pull or thrust. So far the American system has scored one in securing the contract for the Hawkesbury Bridge in Australia. This system affords the best theoretical illustrations of elementary Statics—the subject of Part I. of the present treatise—until the question of the bending moment (it is gratifying to find the term "tendency to break" of the abstract treatises discarded) comes into consideration, when the Old World bridge affords the requisite illustrations.

In Part III., on the "Strength of Materials," the author begins with the resistance of columns and struts to flexure, and here theory and practice have long worked together almost in harmony. The expression "breaking load" of a column—to mean the load which just starts flexure of the column—is apparently usual, but like the expression "tendency to break" should now be discarded for something more suitable. The theoretical strength of a column, according to Euler, which requires the assumption that the column is initially *perfectly* straight, and the actual strength against flexure, are represented in a diagram (p. 160); and the author has shown very ingeniously how the actual state of things encountered in practice can be imitated theoretically by a strut composed of two flanges of unequal elasticity (p. 163). Such a strut will begin to curve immediately as the load is gradually applied, and will thus represent very closely the actual behaviour of a continuous column, as great variations are found experimentally in the elasticity of iron or steel in specimens cut from one piece of metal (p. 167). When crushing or tearing takes place from continually applied pressure or tension, only empirical formulæ are suitable; but, as in actual structures the stress is kept by Board of Trade rules much below the elastic limit, the theoretical equations depending essentially on Hooke's law, that Tension and Extension are in the ratio of the Elasticity of the material, may be employed. Even with the low stresses permissible by law, Wöhler's researches on the fatigue of metals show that permanent deformation may keep on accumulating, and, in consequence, modern engineering practice is in some respects not so daring as formerly. Gordon's empirical rules (§ 124) (originally due to Tredgold) have been shown by Prof. J. H. Cotterill to rest on a theoretical basis, if the compression of the material due to the thrust previous to flexure is taken into account.

For very long spans, the only two rival methods of construction are the cantilever and the suspension principles, of which the Forth Bridge and the Brooklyn Bridge are the great respective examples. In the Cantilever method we build out equally on each side of a pier, so as always to preserve stable equilibrium, while in the suspension method the roadway is suspended from the chains or steel ropes. The chief drawbacks of the suspension principle, its defect of stiffness and great sensibility to changes of temperature, are shown by the author to be avoidable by the system of bracing in his "rigid suspension bridge" (Fig. 22).

The disastrous fall of the Tay Bridge Viaduct in a hurricane has forcibly redirected the attention of engineers to the importance of the theory of wind-pressure and wind-bracing (Chapter XXIV.), and now we may feel secure that in the new Tay Bridge of Mr. Barlow, as well as in all recent structures, ample allowance of strength is provided for against the effect of wind.

The book is copiously illustrated with excellent diagrams of real practice in the construction of bridges, based on the theories of the text, and should prove not only an indispensable hand-book of the practical engineer, but also a stimulating treatise to the student of mathematical mechanics and elasticity.

A. G. GREENHILL.

TWO FRENCH BOOKS.

Les Pygmées. Par A. de Quatrefages.

Les Ancêtres de nos Animaux, dans les Temps Géologiques. Par Albert Gaudry. (Paris : J. B. Baillière et Fils, 1887–88.)

THESE two works form two volumes of Baillière et Fils' "Bibliothèque Scientifique Contemporaine." The first, by the eminent Professor of Anthropology at the Jardin des Plantes at Paris, treats of the Pygmies, a diminutive race of mankind known to the ancients, alluded to by Homer, insisted upon as really existing by Aristotle, next believed to be but myths, and now established as a veritable race of the human kind. The author accepts for them the terms, suggested by Hamy, of Negritos and Negrilles, the latter being confined to the African Pygmies, and the former to those of the Asiatic Isles.

Avowedly a compilation, this little volume has all the peculiar charm that distinguishes Prof. Quatrefages' writings, and abounds with much curious and interesting details. The first chapter treats of the Pygmies from an historic point of view; the second, third, and fourth, of the Negritos, they being exclusively insular. The Negritos are to be found in New Guinea, and all over the Melanesian Archipelago, as far as Fiji; but, while the typical Negrito is confined to this area, conquest, emigration, and slavery have spread the race to Timor, Ceram, Bouro, Gilolo, to the western shores of Borneo, and so to other islands of the Pacific Ocean. Northwards they can be traced to the Carolines, and southwards to New Zealand where they preceded the Maoris. Mr. Ten Kate reports a Melanesian skull found in the little Isle of Santo Spiritu, off the coast of California. To the northwards they can be traced to the Loochoo Isles, Formosa, &c., while their western limits seem to be the Nicobar and Andaman Islands.

The question of the mixing of races on the borders of their distribution is discussed, and a good deal of recent information on this subject is given. The various modifications dependent on the wide range of distribution are also investigated, and the manners and habits of the several groups are described at some length. Good copies of photographs of native heads and figures are appended.

Chapter VI. treats of the Negrilles, or African Pygmies, the details of the Akkas, Tobbo and Chairallah, reared in Italy by Count Miniscalchi Erizzo being full of interest. The last chapter is devoted to the Bushmen of the Cape, and in connection with them there is an account of the Hottentots. The volume has thirty-one figures intercalated with the text.

The second work is by an equally well-known writer, —though of a very different school from that of Prof. Quatrefages—Prof. Albert Gaudry, also a Member of the Institute, and the Professor of Palæontology at the Museum. Well known for his able writings, and for his liberal and modern views on science, he has in this little volume given us a most delightful account of his ideas on the origin and development of the Mammalia during geological time. The volume begins with a chapter on the history of the progress of palæontology, followed by one on evolution and Darwinism. Though a disciple of D'Archiac, who was a strong opponent of Darwin's views, Prof. Gaudry read "The Origin of Species" with the most passionate admiration, and his labours since then have very materially helped to complete the palæontological record. The third chapter is devoted to the subject of the evolution of the Mammalia in geologic time; the fourth introduces us to the author's researches at Pikermi, where, as he tells us, he spent some of the most pleasurable moments of his life, engaged in excavating the remains of the quadrupeds which in times long ago roamed at liberty over the plains of Greece. Here were found an assemblage of animals of large size, such as has never been found before within so limited an area. Beautiful figures of many of these are given, and their relations to existing forms are explained. In another chapter we find an account of similar researches carried on at Léberon, near Cucuron (Vaucluse), where the remains were chiefly those of Herbivores, and an interesting table is added of the succession of the terrestrial Mammalia in France during the Tertiary period. In a concluding chapter there are some short sketches of the well-known palæontologists of the Museum: Alcide D'Orbigny, D'Archiac, Edouard Lartet, followed by a description of the fine new gallery for fossil forms at the Museum.

OUR BOOK SHELF.

The Elements of Graphical Arithmetic and Graphical Statics. By John Y. Gray and George Lowson, M.A. (London and Glasgow: W. Collins, Sons, and Co., 1888.)

IN the year 1871, Prof. Crofton, F.R.S., explained before the London Mathematical Society his diagrams illustrative of the stresses in Warren and lattice girders, and in the course of his remarks said that he had not found anything to help him in English text-books, and referred to papers by Profs. Rankine and Clerk-Maxwell. It was at this meeting (April 13) that Prof. Henrici drew attention to a work then little known in this country, viz. Culmann's "Graphische Statik"—"l'excellente 'Graphische Statik' de M. Culmann" (Prof. Cremona)—and showed that Prof. Crofton's constructions had been anticipated and the methods applied to a very wide range of subjects. On this occasion also Prof. Henrici illustrated the subject by a simple and ingenious notation. He subsequently drew up an abstract of Culmann's work (1866), which was printed in the Appendix to vol. iii. of the above-named Society's Proceedings (pp. 320–22). The work is now well known, and its methods are very generally employed by engineers, and are the subject of lectures in more than one of our Colleges.

The object of the book before us is to give an elementary account of the fundamental principles of the subject in a handy and cheap form, as well as to discuss some simple examples of their application.

The first part—which gives an explanation of graphical methods, illustrates graphical arithmetic, and shows how to represent areas and volumes by lines—is very carefully and clearly worked out, and leads one to see that this part of the subject might well come in at a fairly early date in school-work. Our idea is that the second part, "Graphical Statics," would be improved by more fullness of detail. It comprises an account of the following matters: kinematics, forces in one plane acting at a point, the funicular polygon, resolution of forces, moments, couples, bending moment and shearing force in a simple beam, rolling loads, framed structures, effects of wind-pressure on roofs, bridge-girders, and centres of gravity.

We have noted only two or three typographical errors. The notation employed is one most frequently termed "Bow's notation" in this book, from its having "been brought into use by Robert H. Bow, Esq., C.E.," but a note states that "the method seems, however, to have been first suggested by Prof. Henrici." We presume that Prof. Henrici's notation was the one we have referred to in the opening paragraphs of this notice. The immediate object of the book is to furnish help to students preparing for the South Kensington Examinations and for those of the City and Guilds of London Institute.

The Manual Training School. By C. M. Woodward. (Boston: D. C. Heath and Co., 1887.)

MR. WOODWARD has by no means a high opinion of the results of the efforts that have hitherto been made in European countries to promote technical education. In 1885 he spent five months in examining "trade schools" on this side of the Atlantic, and all the schools visited by him, with the exception of the French Government school at Châlons, disappointed him. He admits that they have "many excellent features"; but their manual training is generally, he holds, "very narrow," and he condemns "their long daily sessions, their long terms, and the conventional nature of their curricula." Manual training, according to Mr. Woodward, is in a much more flourishing condition in America. There it has been introduced "not for a trade or a profession, but for the healthy growth and vigour of all the faculties, for general robustness of life and character"; and he is of opinion that it has been developed in a way that places it "far in advance of any model in a foreign land." Whether or not this comparative estimate is accurate, no one who reads Mr. Woodward's book will dispute that the Americans have begun to understand thoroughly the importance of technical instruction, and that the leaders of opinion on the subject have done much to diffuse enlightened ideas as to the true aims and methods of manual training. Unfortunately, Mr. Woodward has not the art of presenting facts and arguments in an attractive style. He has, however, brought together a great mass of useful information about a subject of pressing importance, and his work, although relating chiefly to institutions founded in his own country, ought to find readers in England as well as in the United States. He does not enter, in detail, into the theory and practice of manual training in primary and grammar schools. He limits himself to the training of pupils beyond the age of fourteen. The value of the work is increased by a number of good woodcuts illustrating shop exercises in woods and metals.

The Method of Creation. By Henry W. Crosskey. (London: The Sunday School Association, 1888.)

THIS little volume belongs to a series of "Biblical Manuals," edited by Prof. J. Estlin Carpenter. With the polemical parts of the book we have, of course, nothing to do. In the chapters in which Mr. Crosskey devotes himself simply to the exposition of scientific truths he writes with full knowledge of his subject and in a clear and pleasant style. "How 'dry land' was formed" is the subject of an excellent chapter, in which the writer brings together some of the more striking of the facts which prove that rocks have been formed by various agencies, that there is no single period at which any kind of rock has been specially produced, that the crust of the earth consists of rocks in ordered succession, and that there has been an unvarying order in the succession of rocks. There are also good chapters on the history of plants and animals, and on the antiquity of the human race.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Coral Formations."

DR. GUPPY's letter shows that I have not been sufficiently explicit on the subject of the formation of atolls, yet I cannot well understand that I have been obscure on the subject of his first question. Surely it is a sufficient reason for rejecting the theory of subsidence as applied to the Chagos Group that I fancy myself, in conjunction with M. Spurs, to have detected evidences of elevation in Diego Garcia. Darwin laid great stress on the character of the Great Chagos Bank as affording evidence of his theory of subsidence; he considers it to be an atoll drowned by a too rapid act of subsidence; but, as I have pointed out, if this were so it is impossible to understand how two atolls such as the Great Chagos Bank and Centurion's Bank could have been thus destroyed without Six Islands or Egmont's Atoll, which lies directly between them, being involved in their destruction. Further, the raised atolls north of Madagascar are unquestionable proofs of upheaval in this region, yet in the same region are low-lying atolls, atoll-shaped reefs awash, and submerged atoll-shaped banks. Clearly the theory of subsidence does not apply to these groups, and I do not see any reason for supposing that the Laccadive and Maldive Islands have been formed differently to the other atolls in the Indian Ocean, though I am unable to bring forward any fresh arguments with regard to them.

Secondly, because I do not agree with Mr. Murray in thinking that lagoons are due largely to the solvent action of sea-water, it is no reason that I should disagree with other parts of his theory. Indeed, after Dr. Guppy's striking observations at Santa Anna and other islands, it would be idle to deny that organic deposits have formed the bases of many atolls, perhaps of all. It did not seem to me necessary to deal with this part of the subject, because as a resident on an atoll without the means of making sectional soundings I had nothing new to say on the subject.

Perhaps you will allow me space to add that before reading my paper I had not had the advantage of meeting Mr. Murray. I have since had that advantage, and on comparing notes with him I find that I am much more in accord with him than my paper would seem to show. I still maintain my point that the rate of organic growth in the lagoon of Diego Garcia is sufficient to counterbalance the solvent action of the sea-water. In other points I agree with him, and believe that my observations confirm his view that atolls tend to spread outwards like a fairy-ring. Mr. Murray has convinced me that I laid undue stress on the direct influence of currents in determining the growth of corals, and this section of my paper was in consequence omitted in the account which appeared in the columns of NATURE. Judging from the local effects which I observed at Diego Garcia, where currents often swept through narrow channels with great force, and from Prof. Moseley's account of the oceanic currents sweeping past St. Paul's rocks, I was led to an exaggerated estimate of the rate of oceanic currents. No doubt a current running at the rate of some thirty-five miles in the day would modify or retard coral growth, but such currents are only found in narrow passages. G. C. BOURNE.

I LATELY discussed Murray's theory of coral formation with a class of boys and girls (fourteen to sixteen years of age), and *they* raised two questions which I am unable to answer. (1) If sea water dissolves the coral near the surface at such a rate as to form a lagoon, why does it not dissolve the limestone foundation even more rapidly? (2) After a reef has progressed a considerable distance from the shore, and a channel of open water is formed between, why should not the reef extend back again shorewards? How could such a channel as exists between Australia and its Great Barrier Reef ever have been kept open? These seem to be valid and serious objections: will some expert be kind enough to answer them? CHARLES R. DRYER.

Fort Wayne, Indiana, U.S.A., April 16.

Density and Specific Gravity.

THE point raised by Mr. Cumming in last week's NATURE (vol. xxxvii. p. 584), as to the use of the words density and specific gravity is, it seems to me, of some importance. For many years past I have, in my lectures, taken the law into my own hands in this matter, and, defining density as the mass of unit volume, I have defined specific gravity, in the way Mr. Cumming suggests in the last paragraph of his letter, as the weight of unit volume (or rather, lest I should cause any to offend against the examiner, I have thus defined *absolute* specific gravity, or specific gravity proper, and have pointed out that the definition commonly given was the definition of *relative* specific gravity). We thus get the parallel relations—

$$M = \rho V \text{ and } W = sV,$$

also

$$W = gM \text{ and } s = g\rho.$$

Thus regarded, specific gravity is to density just what weight is to mass. When force is expressed in absolute units of any kind, specific gravity and density must of course have different numerical values, just as weight and mass have. But in the very large number of cases in which weights are the only forces that have to be considered, and in which it is not needful to take account of the small changes of weight dependent on changes of geographical position, the local weight of the unit of mass may be conveniently taken as the practical unit of force—that is, we may take $g = 1$. In all such cases we have, *numerically*, weight = mass, and specific gravity = density, though the idea of weight is essentially different from that of mass, and the idea of specific gravity from that of density.

Of course, as Mr. Cumming points out, when specific gravity is defined as weight of unit volume, its numerical value for a given substance depends on what is taken as unit of weight and what as unit of volume. With the weight of 1 pound avoirdupois and the cubic foot as units, the specific gravity of water becomes 62·5, and that of platinum 1312·5, instead of 1 and 21 as given in the ordinary tables of (relative) specific gravities. If, on the other hand, we take as unit of weight the weight of unit volume of the standard substance, as is done when weights are expressed in grammes and volumes in cubic centimetres, or weights in kilogrammes and volumes in litres, absolute specific gravities and relative specific gravities become equal, and the ordinary specific gravity tables can be used for practical purposes, which is *one* of the great advantages to be gained by using the metrical system of weights and measures. With any other system, the numbers given in the tables require to be multiplied by the specific gravity of water—that is, they must be translated into absolute specific gravities—before they are of use for almost any real calculation, such as occurs either in experimental physics or in engineering practice. For instance, we weigh a measured length of copper wire and want to know its diameter, or we weigh the quantity of mercury that fills a glass bulb of which we require the capacity, or that fills a measured length of a tube of which we require the bore; or an engineer compares his pressure-gauge against a mercury-manometer in order to convert its indications into pounds-weight per square inch; or he has to calculate the pressure exerted by a brick wall so many feet high, or the weight of a mass of rock of so many cubic feet. In all these cases it is the absolute specific gravity that comes into account; it is no use to tell us that copper is 8·9 times as heavy as water, and mercury 13·6 times as heavy, unless we are told how heavy the unit volume of water itself is.

I maintain, in short, that the weight of unit volume of a substance is a quantity of very great practical importance, for which specific gravity is a very suitable name, whereas the ratio usually defined as specific gravity is of little or no use outside examination questions, and that if it needs a name it should be called relative density.

Further, my experience is that the definition here advocated presents considerable advantages from the point of view of systematic teaching. G. CAREY FOSTER.

University College, London, April 21.

JE crois que la notion de *specific gravity* donnée par M. Cumming dans NATURE du 19 avril (vol. xxxvii. p. 584) est de nature à puzzler les étudiants plus encore que la *vraie* définition physique de la densité.

La densité d'un corps est le rapport de sa masse à son volume—

$$\rho = \frac{M}{V}.$$

Dans le système C.G.S. la densité doit donc être exprimée en *grammes masse par centimètre cube* (voy. Everett, "Units and Physical Constants"). Le poids spécifique est le rapport du poids d'un corps à son volume et devrait être exprimé, dans le système C.G.S. en *dynes par centimètre cube*. Mais il y aurait alors le grave inconvénient pratique à cette définition *rigoureuse* que le poids spécifique varierait avec *g*, accélération due à la pesanteur, tandis que la densité resterait constante.

La confusion provient de ce que le mot *weight*, comme le mot *poids* en français, s'applique indistinctement à la *masse* d'un corps en grammes-masse et à la force qu'exerce la pesanteur sur le corps exprimée en grammes.

La solution logique est de supprimer le mot *poids* du langage, à cause de son double sens, et de ne parler que de la *masse* ou de la *force* exercée par la pesanteur, suivant que l'un ou l'autre facteur intervient dans les calculs.

En tout cas, exprimer le poids spécifique en livres ou en grammes est aussi absurde que d'exprimer les vitesses en mètres, et la puissance (*power*) d'une machine en ergs ou en *foot-pounds*. Le respect de l'homogénéité des formules est la condition essentielle des définitions des quantités physiques, et cette homogénéité n'est pas respectée dans la définition donnée par M. Cumming. E. HOSPITALIER.

Paris, le 23 avril.

The Ignition of Platinum in Different Gases.

AN abstract appeared a few weeks ago in NATURE relating to the "Occlusion of Gases by Platinum and their Expulsion by Ignition," which induces me to mention some curious results obtained by Mr. Lowndes and myself by the ignition of platinum in different gases. We were led to the experiments by another investigation on the behaviour of carbon at high temperatures in various gases. We find that when a platinum wire is heated to nearly melting by a current in an atmosphere of chlorine, the walls of the glass vessel become covered with a yellow deposit, which is insoluble in water, but dissolves in hydrochloric acid, and then, after addition of a little nitric acid, gives all the reactions of platinic chloride. The yellow deposit is in fact platinous chloride. At the same time the thick part of the platinum wire conveying the current, and which was not heated very highly, became incrusted with very fine long crystals of platinum. Some of these were more than the sixteenth of an inch in length, and apparently considerably more were located on that end of the thick wire leading to the negative pole than on the other.

There was also a very decided but lambent flame playing around the ignited and part of the cooler wire during the passage of the current. The arrangement used was a wide-necked flask, stopped with a glass bulb, through which a delivery-tube for the chlorine, and the two No. 12 platinum wires leading the current, passed. The ignited parts of the wire are little coils of No. 24 wire separated by a 1-inch piece of No. 12. On heating the flask externally up to the softening of the glass, the appearance of a flame around the wire increased slightly.

On repeating the experiment with bromine, very nearly the same effects were observed. The amount of platinous bromide was much less than in the case of the chloride, but the flame appearance was very much more pronounced. On passing chlorine into the bromine, so as to form chloride of bromine, both the flame appearance and the action on the platinum were largely increased. With iodine in the flask, vaporized by heating externally, little chemical action on the platinum was observed, only the slightest deposit being formed of a platinum-iodine compound on the glass; but, on passing chlorine into this also, a still more vigorous action on the metal took place, the deposit containing only chlorine and platinum. The flame appearance filled the entire flask. The spectrum of these flames shows no lines in any case. They are all continuous. The largest crystals of platinum were obtained with the ICl_3. Bromide of iodine behaved like iodine.

We have tried a number of other substances in a similar manner. Oxygen, sulphur, sulphur dioxide, nitric oxide, mercury vapour gave negative results as far as we could see. With hydrochloric acid some $PtCl_2$ was formed, but no flame appearance. Phosphoric chloride gave a slight flame, and some $PtCl_2$; but phosphorus is liberated, and then unites with the platinum, melting it. A current of very dry hydrogen fluoride was passed through the flask; before the wire was ignited no action on the glass of the flask was apparent, but almost immediately on passing the current the glass became much corroded by, probably, liberated fluorine. Owing to the flask breaking, we cannot say if platinous fluoride was formed.

With silicon fluoride a singular action took place, the wire, especially the negative half, becoming covered with long semi-transparent crystals of, we think, silicon. The silicon fluoride was very dry, and passed for a long time through the flask without any action until the wire was ignited, when simultaneously with the production of these crystals the glass vessel became much corroded. A small quantity of a soluble platinum salt was formed at the same time. We are continuing these experiments.

We do not think the platinum salts formed in this way are simply shot out by "volcanic" action, as they are quite uniformly spread over the sides of the glass vessel, and seem to be really volatile at the temperature and under the conditions. We have failed to find any record of platinum salts being volatile when heated under ordinary conditions, but it is probable that in the presence of free halogen they would be volatile.

Whether there be any true electrolytic action in these cases we are not at the moment prepared to say.

Royal Military Academy. W. R. HODGKINSON.

"The Nervous System and the Mind."

WILL you allow me to account for one or two of the discrepancies in my book which your very able reviewer points out in the current issue of NATURE?

He cannot reconcile the statement that "everyone nowadays admits that the evolution of mind and the evolution of the nervous system have proceeded *pari passu*, and are indeed but two aspects of the same process," with the further statement that "this way of studying them is so greatly neglected, is indeed derided and scouted." It is pointed out, however, in the passage from which he quotes, that the latter charge is laid at the door of my brother alienists only; while the former statement applies to psychologists at large.

Were it worth while, I could substantiate my charge by chapter and verse, but as the general movement is at last beginning in the direction I advocate, to do so would be to cause the cry from the wilderness to approximate too much to the character of the voice of chanticleer.

Your reviewer states, as if in controversion of my doctrine, that "experienced alienists tell us they find it necessary to admit a moral insanity with an average amount of intelligence." This I have never denied. My position is not that in "moral insanity" intelligence is deficient in amount. What I say is, that in "moral insanity" intelligence is always *disordered.* Disorder of intelligence is very different from deficiency of intelligence. CHAS. MERCIER.

Catford, S.E., April 23.

I AM glad that Dr. Mercier has found so little to complain of in the review of his recent work. I am bound to accept his explanation of the discrepancy I ventured to point out, although, on re-reading the two apparently antagonistic passages again, I do not find the distinction between psychologists and alienists, to which he now refers, clearly stated. The expression "everyone" (p. 4) appears to include both. Dr. Mercier's "brother alienists" are, it seems, excluded from the class that can grasp the truth that the evolution of mind and the nervous system are but two aspects of the same process, and belong to that uninformed class that "deride and scout" it. I certainly should have hesitated to understand this to be the author's meaning, but, being so, I must leave his benighted *confrères* to settle their account with him. They may perchance think that in this reading of the passage, "the voice of chanticleer" has already become associated with the *vox clamantis* in the wilderness!

In regard to the association of moral insanity with an average amount of intellect, I would only observe that the brother alienists of Dr. Mercier, including Dr. Maudsley, contend that, not only may this be met with, but that moral insanity may co-exist with an undisordered intelligence. Dr. Mercier's contention that "in moral insanity intelligence is always disordered" would therefore be still in conflict with the experience of some experienced alienists, which was the position I took.

Both these points, however, are only small matters compared with the general subject-matter of the work under review, and I repeat that it is gratifying to find there does not appear to have been any important mis-statement of Dr. Mercier's views in the friendly criticism of THE REVIEWER.

April 24.

Nose-Blackening as Preventive of Snow-Blindness.

MY friend Mr. Edmund J. Power sends me the following account of what appears to me to be an interesting fact. I should like to obtain suggestions from physiologists as to the possible explanation of the phenomenon, on the assumption that the blackening of the nose and eyelids really does prevent the injurious action of sunlight on the eyes; and further, I should like to know whether (quite apart from the fact of its utility or futility) the custom has possibly a remote origin in some ceremony or ritual. E. RAY LANKESTER.

"Can you or some of your friends explain the following?

"When in Colorado shooting the end of last year, my friend had a very bad attack of snow-blindness, caused by a long march on snow with bright sun. My eyes also were very bad the next day and caused much pain.

"Some days after I was under similar circumstances, when my guide stopped, and taking some burnt wood from a stump blackened his nose and under the eyes well down on the cheek-bone.

"On asking him the reason, he told me it stopped snow-blindness, and as the glare was very strong I did the same, and found immediate relief.

"I did this all the time I was out, and never found the snow affect my eyes in any way.

"Everyone I spoke to about it could give no reason for it, but all used it on the march. Some use glasses, but, as my man remarked, 'glasses cost dollars, dirt nothing.'

"Perhaps some of your friends can enlarge on the subject, as it is of great interest to me, and may be so to Alpine people, as glasses are hot to climb in, and from my own experience it is not easy to stalk in glasses and then take them off and shoot."

"Antagonism."

THE author of "The Correlation of the Physical Forces" has, I am sure, our sympathy when he relates how he has been forestalled by Prof. Huxley.

As Sir William Grove subsequently says that "it is always useful to know the truth," he will, perhaps, excuse my suggesting that his views upon antagonism as pervading the universe have been anticipated in a work published more than a quarter of a century ago. I allude to "First Principles," and more especially to the chapter in it upon "The Rhythm of Motion," in which the effects of antagonist forces are shown to be everywhere present, and are copiously illustrated and expounded from the stand-points of astronomy, geology, biology, psychology, and sociology. After reading this chapter, and especially its concluding sentence—"Given the co-existence everywhere of antagonist forces, a postulate which, as we have seen, is necessitated by the form of our experience"—we cannot, I think, but add another eminent name to that of Prof. Huxley as anticipating Sir W. Grove: it is that of Mr. Herbert Spencer.

F. HOWARD COLLINS.

Churchfield, Edgbaston, April 29.

Sense of Taste.

THE curious difference between male and female observers in detecting feeble traces of quinine, sugar, acid, &c., in water as mentioned in NATURE on p. 557 (vol. xxxvii.), is possibly owing to the sense of taste being injured in the males by the use of tobacco.

I have had occasion to apply delicate tests of smell and taste, and I find that even moderate smokers are unable to detect odours and tastes that are quite distinct to non-smokers.

Dunstable. W. G. S.

SUGGESTIONS ON THE CLASSIFICATION OF THE VARIOUS SPECIES OF HEAVENLY BODIES.[1]

III.

III.—SUB-GROUPS AND SPECIES OF GROUP I.

I. SUB-GROUP. NEBULÆ.

HAVING, in the preceding part of this memoir, attempted to give a general idea of that grouping of celestial bodies which in my opinion best accords with our present knowledge, and which has been based upon the assumed meteoric origin of all of them, I now proceed to test the hypothesis further by showing how it bears the strain put upon it when, in addition to furnishing us with a general grouping, it is used to indicate how the groups should be still further divided, and what specific differences may be expected.

The presence or absence of carbon will divide this group into two main sub-groups.

The first will contain the nebulæ, in which only the spectrum of the meteoric constituents is observed with or without the spectrum of hydrogen added.

It will also contain those bodies in which the nebula spectrum gets almost masked by a continuous one, such as Comets 1866 and 1867, and the great nebula in Andromeda.

In the second sub-groups will be more condensed swarms still, in which, one by one, new lines are added to the spectra, and carbon makes its appearance; while probably the last species in this sub-group would be bodies represented by γ Cassiopeiæ.

Species of Nebulæ.

I have elsewhere referred to the extreme difficulty of the spectroscopic discrimination in the case of the meteor-swarms which are just passing from the first stage of condensation, and it may well be that we shall have to wait for many years before a true spectroscopic classification of the various aggregations which I have indicated, can be made.

It is clear, then, from what has gone before that in each stage of evolution there will be very various surfaces and loci of collisions in certain parts of all the swarms, and we have already seen that even in the nebulosities discovered by Sir Wm. Herschel, which represent possibly a very inchoate condition, there are bright portions here and there.

If the conditions are such in the highly elaborated swarms and in the nebulosity that the number of collisions in any region per cubic million miles is identical, the spectroscope will give us the same result. In the classification of the nebulæ, therefore, the spectroscope must cede to the telescope when the dynamical laws, which must influence the interior movements of meteoric swarms, have been fully worked out. The spectroscope, however, is certainly at one with the telescope in pointing out that so-called planetary nebulæ are among the very earliest forms—those in which the collisions are most restricted in the colliding regions. The colour of these bodies is blue tinged with green; they do not appear to have that milkiness which generally attaches to nebulæ, and the bright nebulous lines are seen in some cases absolutely without any trace of continuous spectrum. In higher stages the continuous spectrum comes in, and in higher stages still possibly also the bands of carbon; for in many cases Dr. Huggins in his important observations has recorded the weakness of the spectrum in the red, or in other words the strengthening of the spectrum in the green and blue exactly where the carbon bands lie.

But in all the bodies of Group I. which possess forms visible to us in the telescope, it would seem proper that their classification should depend mainly—at present at all events—upon their telescopic appearance, and there is very little doubt that a few years' labour with the new point of view in the mind of observers armed with sufficient optical power, will enable us to make a tremendous stride in this direction; but it seems already that this must not be done without spectroscopic aid. For instance, if what I have previously suggested as to the possible origin of the planetary nebulæ be accepted, it is clear that in those which give us the purest spectrum of lines, one in which there is the minimum of continuous spectrum, we find the starting-point of the combined telescopic and spectroscopic classification, and the line to be followed will be that in which, *cæteris paribus*, we get proofs of more and more condensation, and therefore more and more collisions, and therefore higher and higher temperatures, and therefore greater complexity in the spectrum until at length true stars are reached.

When true stars are reached those of the cluster appear nebulous in the telescope in consequence of its distance; the spectroscope must give us indications by absorption.

It is not necessary in this connection, therefore, to refer to undoubted star clusters, as the presence of absorption will place them in another group; but the remark may be made that it is not likely that future research will indicate that new groupings of stars, such as Sir Wm. Herschel suggests in his paper on the breaking up of the Milky Way, will differ in any essential particular from the successive groupings of meteorites which are watched in the nebulæ. Space and gravitation being as they are, it is not necessary to assume that any difference of kind need exist in the method of grouping formed stars and meteoric dust; indeed there is much evidence to the contrary.

II. SUB-GROUP. BRIGHT-LINE STARS.

It might appear at first sight that the distribution of bright-line stars among various species should be very easy, since a constant rise of temperature should bring out more and more lines, so that the species might be based upon complexity of spectrum merely.

But this is not so, for the reason that the few observations already recorded, although they point to the existence of carbon bands, do not enable us to say exactly how far the masking process is valid. Hence in the present communication I content myself by giving some details relating to maskings, and the results of the discussions, so far as they have gone, in the case of each star. I shall return to the line of evolution in a later paper.

Masking of Radiation Effects produced by Variations of Interspacing.

I have already stated that carbon bands are apt to mask the appearance of other spectral phenomena in the region of the spectrum in which they lie. In this way we can not only account for the apparent absence of the first manganese fluting, while the second one is visible, but it is even possible to use this method to determine which bands of carbon are actually present. There is another kind of masking effect produced in a different way, and this shows itself in connection with sodium. It is well known that when the temperature is low, D is seen alone, and if seen in connection with continuous spectrum the continuous spectrum is crossed by either dark or bright D, according to the existing circumstances.

I showed some years ago that the green line of sodium, not the red one, is really visible when sodium is burned in the bunsen burner. It is, however, very much brighter when higher temperatures are used, although when bright it does not absorb in the way the line D does.

Now, if we imagine a swarm of meteorites such that in the line of sight the areas of meteorite and interspace are

[1] The Bakerian Lecture, delivered at the Royal Society on April 12, by J. Norman Lockyer, F.R.S. Continued from vol. xxxvii. p. 609.

equal, half the area will show D absorbed, and the other half D bright; and in the resulting spectrum D will have disappeared, on account of the equality, or nearly equality, of the radiation added to the absorption of the continuous spectrum. The light from the interspace just fills up and obliterates the absorption.

But if the temperature is such that the green line is seen as well as D; in consequence of its poor absorbing effect there will be no dark line corresponding to it in the resulting spectrum, but the bright green line from the interspace will be superposed on the continuous spectrum, and we shall get the apparently paradoxical result of the green line of sodium visible while D is absent. This condition can easily be reproduced in the laboratory by volatilizing a small piece of sodium—between the poles of an electric lamp. The green line will be seen bright, while D is very dark.

In the bodies in which these phenomena apparently occur—for so far I have found no other origin for the lines recorded 569, 570, and 571—the wave-length of the green sodium line being 5687, such as Wolf and Rayet's three stars in Cygnus and in γ Argûs, the continuous variability of D is one of the facts most clearly demonstrated by the observations, and it is obvious that this should follow if from any cause any variation takes place in the distance between the meteorites.

In all meteoric glows which have been observed in the laboratory, not only D but the green line have been seen constantly bright, while we know in Comet Wells most of the luminosity at a certain stage of the comet's history was produced by sodium. It is therefore extremely probable that the view above put forward must be taken as an explanation of the absence of D when not seen, rather than an abnormal chemical constitution of the meteorites—that is to say, one in which sodium is absent. This may even explain the fact that up to the present time the D line of sodium has not been recorded in the spectrum of any nebula.[1]

Detailed Discussion of the Spectra of some Bright-Line Stars.

These things then being premised, I now submit some maps illustrating this part of the inquiry, although it will be some time before my investigations on the bright-line stars are finished. These maps will indicate the way in which the problem is being attacked, and the results already obtained. To help us in the work we have first of all those lines of substances known to exist in meteorites which are visible at the lowest temperatures which we can command in the laboratory. We have also the results of the carbon work to which reference was made in the previous paper; and then we have the lines which have been seen, although their wave-lengths have in no case been absolutely determined, in consequence of the extreme difficulty of the observation, both in stars and in comets, which I hold to be almost identical in structure.

In the case of each star the lines which have been recorded in its spectrum are plotted in the way indicated in the maps. The general result is that when we take into account the low temperature radiation, which we learn from the laboratory work, not only can we account for the existence of the lines which have been observed, but apparent absorptions in many cases are shown to be coincident with the part of the spectrum in front of a bright carbon fluting.

[1] In the lecture the author here referred to the spectrum of *o* Ceti, as photographed by Prof. Pickering for the Henry Draper Memorial, the slide having been kindly placed at his disposal by the Council of the Royal Astronomical Society. All the bright hydrogen lines in the violet and ultra-violet are shown in the photograph; with the exception of the one which is nearly coincident with H. The apparent absence of this line is in all probability due to the masking effect of the absorption-line of calcium. In this case, then, it appears that the calcium vapour is outside the hot hydrogen, and this therefore was being given off by the meteorites at the time.

A continuation of this line of thought shows us also that, when in these stars the spectrum is seen far into the blue, the luminosity really proceeds first from the carbon fluting, and in the hotter stars, from the hydrocarbon one in addition, which is still more refrangible. In the stars which have been examined so far, the dark parts of the spectrum, which at first sight appear due to absorption, are shown to be most likely caused by the gap in the radiation in that part of the spectrum where there is no continuous spectrum from the meteorites, and no bright band of carbon.

All the observations, it would appear, can be explained on the assumption of low temperature.

Notes on the Maps.

Lalande 13412.—Both Vogel and Pickering have observed the spectrum of this star and have measured the wave-lengths of the bright lines.

Vogel gives a sketch of the spectrum as well as a list of wave-lengths.

Vogel mentions a dark band at the blue end of the spectrum, and gives the wave-length in his sketch as from 486 to 473.

Both observers measure the bright 486 hydrogen (F) line.

Vogel measures a bright line at 540, while Pickering's measure is 545; but Pickering in another star, Arg.-Oeltzen 17681, has measured this line at 540, so there can be little doubt that is the correct wave-length.

Vogel measures a line at 581, but this has not been noticed by Pickering.

The bright part of the spectrum extending from 473 towards the blue with its maximum at 468 is, I would suggest, the carbon band appearing beyond the continuous spectrum, the rest of the carbon being cut out by the continuous spectrum, although 564 asserts itself by a brightening of the spectrum at that wave-length in Vogel's sketch, and by a rise in his light-curve.

The line at 540 is the only line of manganese visible at the temperature of the bunsen burner, while the 581 measurement of Vogel is in all probability the 579 line, the strongest line of iron visible at low temperatures.

In this star therefore we have continuous spectrum from the meteorites, and carbon bands, one of them appearing beyond the continuous spectrum in the blue as a bright band; bright lines of hydrogen, manganese, and iron being superposed on both. There is no absorption of any kind, the apparent dark band being due to defect of radiation.

Vogel's results are given in the *Publicationen des Astrophysikalischen Observatoriums zu Potsdam*, vol. iv. No. 14, p. 17.

Pickering's are published in the *Astronomische Nachrichten*, No. 2376; *Science*, No. 41; and quoted in *Copernicus*, vol. i. p. 140.

2nd Cygnus.—B.D. + 35°, No. 4013.—Messrs. Wolf and Rayet, in 1867, first observed the spectrum of this star, and measured the positions of the bright lines. Micrometer readings and reference lines are given by them from which a wave-length curve has been constructed. The wave-lengths of the bright lines in the star thus ascertained are: 581 (γ), 573 (β), 540 (δ), and 470 (α); the relative intensities being shown by the Greek letters.

"La ligne β est suivie d'un espace obscur; un autre espace très-sombre précède α."

Vogel afterwards examined the spectrum, measured the positions and ascertained the wave-lengths of the bright lines, drew a sketch of the spectrum as it appeared to him, and a curve showing the variation of intensity of the light throughout the spectrum.

The wave-lengths given by Vogel are 582 and 570, and of a band with its brightest part at 464, fading off in both directions and according to the sketch having its red limit at 473. In the light curve Vogel not only shows the 582 and 570 lines, but al-o bright lines in positions which by a curve have been found to correspond to wave-lengths 540 and 636. Vogel indicates in his sketch a dark band extending from 486 to the bright band 473, and an apparent absorption on the blue side of the 570 line, this absorption being ended at 564. These two bands agree in position with the dark spaces observed by Messrs. Wolf and Rayet. The bright band in the blue at 473 is most probably the carbon band appearing bright upon a faint continuous spectrum, this producing the apparent absorption from 486 to 473. If the bright carbon really

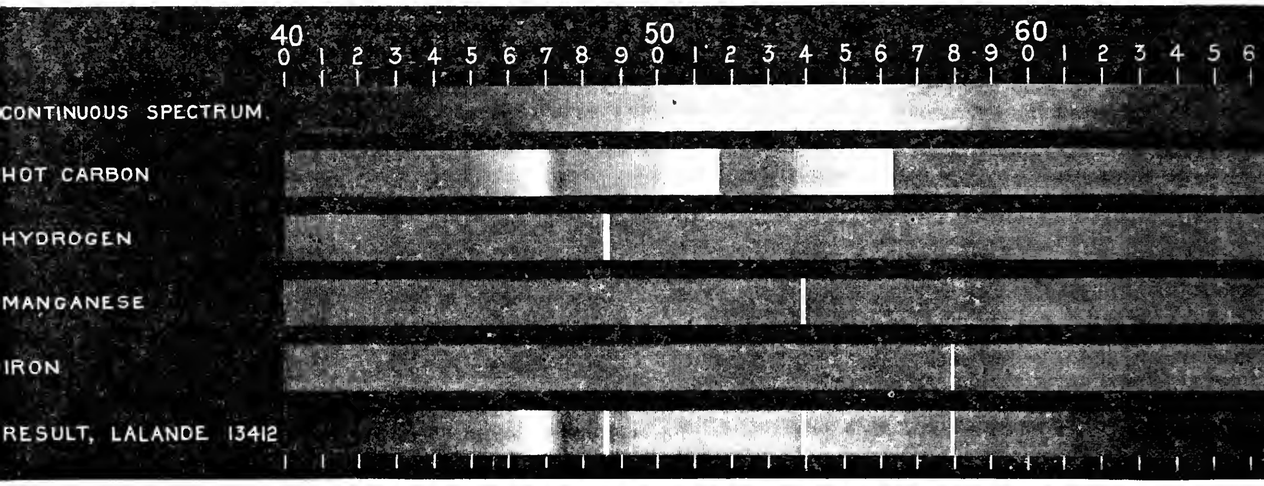

FIG. 4.—Map showing the probable origin of the spectrum of Lalande 13412.

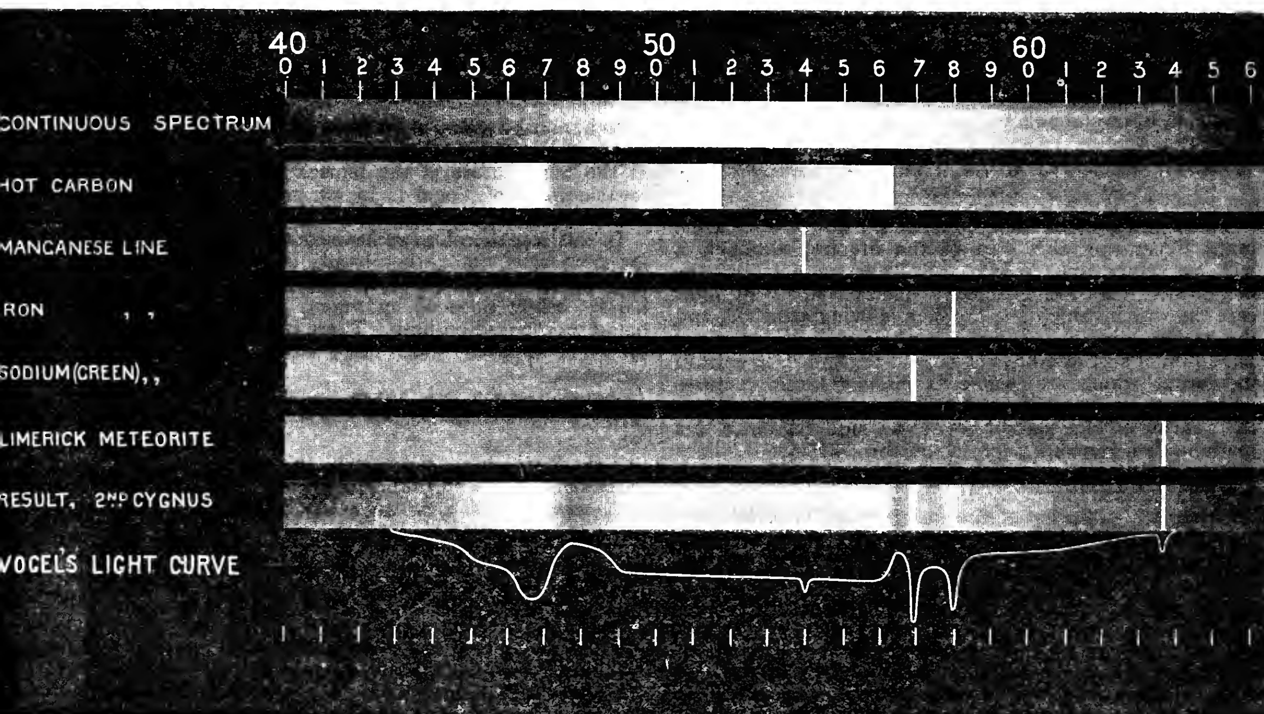

FIG. 5.—Map showing the probable or'gin of the spectrum of Wolf and Rayet's 2nd star in Cygnus.

accounts for the appearance of a dark band between the bright 570 and 564 in this star, all the apparent absorption is explained as due to contrast of bright bands on a fainter continuous spectrum due to red-hot meteorites.

The line at 540 is the only line of manganese visible in the bunsen burner, and the 580 line is the strongest low-temperature iron line. The 570 line is most probably the green sodium line 569, the absence of the yellow sodium being explained by the half-and-half absorption and radiation mentioned in the discussion of the causes which mask and prevent the appearance of the lines in a spectrum.

The line at 636 is in the red just at the end of the continuous spectrum, and as yet no origin has been found for it, although it has been observed as a bright line in the Limerick meteorite at the temperature of the oxyhydrogen blow-pipe.

This star therefore gives a continuous spectrum due to radiation from meteorites, and on this we get bright carbon (with one carbon band appearing separate in the blue), with bright lines of iron, manganese, sodium, and some as yet undetermined substance giving a line at 636 in the oxyhydrogen blow-pipe.

Wolf and Rayet's results are given in the *Comptes rendus*, vol. lxv. p. 292.

Dr. Vogel's are from the *Publicationen des Astrophysikalischen Observatoriums zu Potsdam*, vol. iv. No. 14, p. 19.

The above are only given as examples of the seven bright-line stars explained in the lecture.

(*To be continued.*)

THE ROYAL SOCIETY SELECTED CANDIDATES.

THE following fifteen candidates were selected on Thursday last by the Council of the Royal Society to be recommended for election into the Society. The ballot will take place on June 7, at 4 p.m. We print with the name of each candidate the statement of his qualifications:—

THOMAS ANDREWS, F.R.S.E.,

F.C.S., Assoc.M.Inst.C.E. Ironmaster and Metallurgist. Awarded by the Institution of Civil Engineers, for original metallurgical and physical researches, a Telford Medal and a Telford Premium, Session 1884; again a Telford Premium, Session 1885: and another Telford Premium, Session 1886. Author of the following eighteen papers:—In Proc. Roy. Soc. Lond. (four papers), "Electromotive Force from difference of Salinity in Tidal Streams," "Action of Tidal Streams on Metals during diffusion of Salt and Fresh Water," "Reversals of Electromotive Force between Metals of High Temperatures in Fused Salts," "Observations on Pure Ice and Snow" (a determination of their relative conductivity for heat, and the great contraction of ice at extremely low temperatures, &c.); Trans. and Proc. Roy. Soc. Edin. (four papers), "On Relative Electro-chemical Positions of Iron, Steels, and Metals in Sea Water," "Apparent Lines of Force on passing a Current through Water," "Resistance of Fused Halogen Salts," "Electromotive Force between Metals at High Temperatures"; Proc. Inst. Civ. Eng. (four papers), "On Galvanic Action between Metals long exposed in Sea Water," "Corrosion of Metals long exposed in Sea Water." Author of an investigation on "Effects of Temperature on Strength of Railway Axles," Part I., II., and III., conducted by the author at a cost of nearly £800, to determine on a large scale the resistance of metals to a sudden concussion at varying temperatures down to zero F. Author also of papers "On Variations of Composition of River Waters" (Chem. Soc., 1875), and "On Curious Concretion Balls from Colliery Mineral Waters" (Brit. Assoc. Rep., Chemical Section, 1879), and "On Strength of Wrought Iron Railway Axles" (Trans. Soc. Eng., 1879; a premium of books awarded for this paper). At present engaged on a research "On some Novel Magneto-Chemical Effects on Magnetizing Iron," and "On the Construction of Iron, Steels, and Cast Metals at Low Temperatures, −50° F.," and "On the Viscosity of Pure Ice at −50° F., &c."

JAMES THOMSON BOTTOMLEY, M.A.,

Demonstrator of Experimental Physics in the University of Glasgow. After being several years with Dr. Andrews in Belfast, as pupil, and as assistant afterwards, he acted as Demonstrator in Chemistry in King's College, London, under Dr. W. A. Miller, and subsequently as Demonstrator and Lecturer in Natural Science, under Prof. W. G. Adams, till 1870, when he came to his present post in the University of Glasgow. Author of "Dynamics," for the Science and Art Department; "Hydrostatics," ditto; "Mathematical Tables for Physical Calculations;" Essay on the Progress of Science since 1833 ("Conversations-Lexicon"); all the articles on Electricity and Magnetism in Moxon's "Dictionary of Science." Also of many scientific articles describing his own experimental researches, including "Thermal Conductivity of Water" (Phil. Trans., 1881); "Permanent Temperature of Conductors, &c." (Proc. Roy. Soc. Edin.), &c.

CHARLES VERNON BOYS,

A.R.S.M. Demonstrator of Physics, Normal School of Science and Royal School of Mines. Author and joint-author of the following:—"Magneto-Electric Induction" (Proc. Phys. Soc., 1879 and 1880); "An Integrating Machine" (Proc. Phys. Soc., 1881); "Integrating and other Apparatus for the Measurement of Mechanical and Electrical Forces" (Proc. Phys. Soc., 1882); "Apparatus for Calculating Efficiency" (Proc. Phys. Soc., 1882); "Measurement of Curvature and Refractive Index" (Proc. Phys. Soc., 1882); "Vibrating Electric Meter" (Proc. Roy. Inst. 1883); "New Driving Gear" (Soc. Art. Lect., 1884); and other papers.

ARTHUR HERBERT CHURCH, M.A. (Oxon.),

F.C.S., F.I.C. Professor of Chemistry in the Royal Academy of Arts. Sometime Professor of Chemistry in the Royal Agricultural College, Cirencester. Researches in Animal, Vegetable, and Mineral Chemistry, *e.g.* Turacin, an animal pigment containing copper (Phil. Trans., 1869); Colein, the pigment of *Coleus Verschaffeltii* (Journ. Chem. Soc., 1877); Aluminium in certain Cryptogams (*Chemical News*, 1874); Vegetable Albinism (Journ. Chem. Soc., 1879, 1880, 1886, Pts. I.-III.); New Mineral Species, Churchite, Tavistockite, Bayldonite (*ibid.*, 1865); Namaqualite (*ibid.*, 1870); Analysis of Mineral Phosphates and Arseniates (*ibid.*, 1868, 1870, 1873, 1875, &c., Proc. Roy. Irish Acad., 1882), &c.

ALFRED GEORGE GREENHILL, M.A.,

Professor of Mathematics for the Advanced Class of Artillery Officers at Woolwich. Was Second Wrangler and bracketed Smith's Prizeman in 1870. Has been Moderator and Examiner for the Mathematical Tripos, University of Cambridge, in 1875, '77, '78, '81, '83, '84. Author of "Differential and Integral Calculus" (1886); Article on Hydromechanics in the "Encyclopædia Britannica." Also of the following papers, in the Proceedings of the Royal Artillery Institute:—"Rotation required for Stability of Elongated Projectiles" (vol. x); "Motion in Resisting Medium" (*ibid.*); "Trajectory for Cubic Law of Resistance" (vol. xiv.); "Reduction of Bashforth's Experiments" (vol. xv.); "Siacci's Method for solving Ballistic Problems" (vol. xiv.). In the *Journal de Physique*:—"Sur le Magnétisme induit d'un Ellipsoide creux" (1881). *American Journal of Mathematics*:—"Wave Motion in Hydrodynamics" (vol. ix.). In the *Engineer*:—"Screw-propeller Efficiency" (1886). In the *Quarterly Journal of Mathematics*:—"Precession and Nutation" (vol. xiv.); "Plane Vortex Motion" (vol. xv.); "Motion of Top" (*ibid.*); "Motion of Water in Rotating Parallelopiped" (*ibid.*); "Fluid Motion between Confocal Ellipsoids" (vol. xvi.); "Solution by Elliptic Functions of Problems in Heat and Electricity" (vol. xvii.); "Functional Images in Cartesians" (vol. xviii.); "Complex Multiplication of Elliptic Functions" (vol. xxii.), and others. In *Messenger of Mathematics*:—"Fluid Motion" (vols. viii.-x.); "Lord Rayleigh's Theory of Tennis Ball" (vol. ix.); "Period Equation of Lateral Vibrations" (vol. xvi.); "Sumner lines on Mercator's Chart" (*ibid.*); "Solution of Cubic and Quartic" (vol. xvii.). In the Proceedings of the Cambridge Philosophical Society:—"Rotation of Liquid Ellipsoid" (vols. iii., iv.); "Green's Function for Rectangular Parallelopiped" (vol. iii); "Integrals expressed by Inverse Elliptic Functions (*ibid.*); "Conjugate Functions of Cartesians" (vol. iv.); "Greatest Height a Tree can grow" (*ibid.*); "Complex Multiplication of Elliptic Functions" (vols. iv., v.). In Proceedings Institution Mechanical Engineers:—"Stability of Shafting" (1883).

LIEUT.-GENERAL SIR WILLIAM FRANCIS DRUMMOND JERVOIS, R.E., G.C.M.G.,

Governor and Commander-in-Chief of New Zealand. Distinguished as a Military Engineer. From 1841 to 1848 employed in South Africa, during which time he erected important military works, and added largely to the topographical knowledge of that part of the world, discovering the true feature of the Quathlamba Mountains, and making a minute topographical survey of Kaffraria; his map, published by E. Stanford, being a wonderful delineation of most difficult and rugged country. For nearly twenty years, from 1856 to 1875, employed in the designing and execution of the fortifications of the Empire at a most critical period, when, owing to the introduction of iron armour, a complete revolution took place in matters relating to ships, forts, and artillery. Was a member of the Scientific Commission (1861-62, &c.) appointed to investigate the subject of the application of iron armour to ships and forts. Governor of Straits Settlements, 1875-77. In 1877 selected to advise the Governments of Australia on the defence of their principal harbours. His recommendations have been adopted and carried out. In 1877 appointed Governor of South Australia, and in that capacity, as also in that of Governor of New Zealand (since 1882), has promoted the progress of Science in various ways.

CHARLES LAPWORTH,

Professor of Geology in the Mason Science College, Birmingham; Hon. LL.D. (St. Andr.). Most important contributions to the right understanding of the stratigraphy of the North-West Highlands and the Southern Uplands of Scotland, and investigations of the Palæozoic and other strata, as published in his papers on "The Moffat Series," "The Girvan Succession," "The Stratigraphy and Metamorphism of the Duness and Eriboll District," the "Secret of the Highlands," the "Close of the Highland Controversy," "Discovery of the Cambrian Rocks in the Neighbourhood of Birmingham," and on "The Classification of the Lower Palæozoic Rocks," &c.,—papers published between 1878 and 1887 in the Quart. Journ. Geol. Soc., and the *Geol. Mag.* Also for his Palæontological work, especially among the Rhabdophora, mainly published in six papers between 1873 and 1887. Recipient of the Murchison and of the Lyell Funds, and of the Bigsby Medal of the Geological Society.

T. JEFFREY PARKER,

Professor of Biology. Author of the Memoirs enumerated below. Distinguished as a Comparative Anatomist and as a Teacher. Has introduced an important new method of preserving the skeletons of cartilaginous fishes for museum purposes, and has rendered service to the cause of Science in the Colonies by his creation of the Otago Museum, and by his popular lectures and addresses. He has published thirty-three original papers on Biological subjects in the Proceedings and Transactions of various Societies—Royal, Zoological, Royal Microscopical, &c. Amongst these may be mentioned the following, viz.:—"On the Stomach of the Fresh-water Cray-fish," "On the Stridulating Organ of *Palinurus vulgaris*," "On the Intestinal Spiral Valve in the Genus *Raia*," "On the Histology of *Hydra fusca*," "On the Venous System of the Skate," "On the Osteology of *Regalecus argenteus*," "On the Blood-vessels of *Mustelus antarcticus*," &c.

JOHN HENRY POYNTING, M.A., B.Sc.

Professor of Physics in the Mason College, Birmingham. Author of the following papers:—"On a Method of Using the Balance with great Delicacy" (Proc. Roy. Soc., vol. xxviii.); "On the Graduation of the Sonometer" (*Phil. Mag.*, 1880); "On a Simple Form of Saccharimeter" (*ibid.*, 1880); "On Change of State: Solid-Liquid" (*ibid.*, 1881); "On the Connection between Electric Current and the Electric and Magnetic Inductions in the surrounding Field" (Proc. Roy. Soc., vol. xxxviii.); "On the Transfer of Energy in the Electro-magnetic Field" (Phil. Trans., 1884, Part II.).

WILLIAM RAMSAY,

Ph.D. (Tüb.). F.C.S., F.I.C. Professor of Chemistry, University College, London. President of the Bristol Society of Naturalists, and of the Bristol Section of the Society of Chemical Industry. Distinguished as a Chemist, and especially for his researches in Chemical Physics. Author of the following papers:—"Orthotoluic Acid and its Derivatives" (*Liebig's Annalen*, 1872); "Picoline and its Derivatives" (*Phil. Mag.*, 1876-78); "The Oxidation Products of Quinine and allied Alkaloids" (Journ. Chem. Soc., 1878-79); "Specific Volumes" (*ibid.*, 1879-81); "The Volatilization of Solids" (Phil. Trans., Pt. I., 1884); "The Vapour Pressures of Solids and Liquids" (Phil. Trans., Pt. II., 1884); "A Study of the Thermal Properties of Alcohol" (Proc. Roy. Soc., vol. xxxviii., p. 329); "On Evaporation and Dissociation" (Preliminary Notice, Rep. Brit. Assoc., 1884).

THOMAS PRIDGIN TEALE, M.A. (Oxon.),

F.R.C.S., 1857. Surgeon to the Leeds General Infirmary. Late Lecturer on Surgery, Leeds School of Medicine. Member of the General Medical Council. Eminent as a Sanitary Reformer, and Surgeon and Ophthalmologist. Author of—(*a*) various Papers and Lectures bearing upon Public Health and Sanitary Reforms, among which are:—(1) "Dangers to Health in our own Houses," a Lecture at the Leeds Lit. and Phil. Soc., 1877; (2) "Dangers to Health: a Pictorial Guide to Domestic Sanitary Defects," 4th ed., 1883 (also in French and German); (3) "Economy of Coal in House Fires," 1882; (4) "Address on Health" (dealing with the effects of Modern Educational Systems upon Health), delivered as President of the Health Section of the Social Science Congress at Huddersfield, 1883. (*b*) Papers of value in Surgery and Ophthalmology, extending from 1850 to 1885—(1) "On the Treatment of Lachrymal Obstructions, with suggestions to use Bulbed Probes" (*Med. Times and Gaz.*, 1860); (2) "On the Relief of Symblepharon by the Transplantation of Conjunctiva" (Ophth. Hosp. Rep., vol. iii., and Report of the International Ophthalmic Congress in London, 1872); (3) "On Extraction of Soft Cataract by Suction" (Ophth. Hosp. Rep., vol. iv.); (4) "The Relative Value of Atropine and Mercury in Acute Iritis" (*ibid.*, vol. v.); (5) "Enucleation of Nævus" (Trans. Med. and Chir. Soc., 1867); (6) "On Atrophy induced by Cicatrix" (*Brit. Med. Journ.*, 1867); (7) "On the Stimulation of Hip Disease by Suppuration of the Bursa over the Trochanter major" (Clin. Essay, No. 2, *Lancet*, 1870); (8) "Ovariotomy during Acute Inflammation of the Cyst" (*Lancet*, 1873); (9) "Ovariotomy in extremis" (Clin. Essay, No. 4, *Lancet*, 1874); (10) "Exploration of the Abdomen in cases of Obstruction of the Bowel" (Clin. Essay, No. 5, *Lancet*, 1875); (11) "On the Treatment of Vesical Irritability and Incontinence in the Female, by Dilatation of the Neck of the Bladder" (Clin. Essay, No. 6, *Lancet*, 1875); (12) "The Surgery of Scrofulous Glands" (*Med. Times and Gazette*, 1885).

WILLIAM TOPLEY,

F.G.S., Assoc.Inst.C.E. Student of the Royal School of Mines, 1858-61. For twenty years engaged in the Geological Survey; and has mapped parts of Kent, Surrey, Durham, Northumberland, &c., with illustrative sections and memoirs. Author of a general Memoir on the Geology of the Weald of Kent and Sussex. Author of various papers in Quart. Journ. Geol. Soc.; of a paper on the Relation of Geology to Agriculture, in Journ. Roy. Agric. Soc.; and on the Channel Tunnel, in *Quart. Journ. Sci.* Assisted Dr. Buchanan in a Report to the Privy Council Medical Officer, on the Distribution of Phthisis as affected by dampness of soil. Secretary (1872-81) of the Geol. Section of Brit. Assoc. Member for England of the Committee for preparing an International Geological Map of Europe. Editor of the *Geological Record*. President, Geologists' Association. Author of Report on "The National Geological Surveys of Europe" (Brit. Assoc., 1884).

HENRY TRIMEN, M.B. (Lond.),

F.L.S. Director of the Royal Botanic Gardens, Ceylon. Devoted to the study of Botany, systematic, descriptive, economic, geographical, and historical. Editor of the *Journal of Botany*, 1872-79. Author (in conjunction with Mr. W. T. Thiselton Dyer, F.R.S.) of "Flora of Middlesex" (1869); of the Botanical portion of Bentley and Trimen's "Medicinal Plants" (1875-80); and of more than sixty papers on botanical subjects, including:—"Descriptions and Critical Observations on the Successive Additions to the British Flora" (*Journ. of Bot.*, 1866-79); "The *Juncaceæ* of Portugal" (*ibid.*, 1872); "*Spenceria*, a new genus of *Rosaceæ*" (*ibid.*, 1879); "*Phyllorachis*, a new genus of *Gramineæ*" (*ibid.*); "Notes on *Oudneya* and *Boea*" (Linn. Soc. Journ., 1877-79); "Systematic Catalogue of the Phanerogams and Ferns of Ceylon" (Journ. Asiat. Soc. Ceylon, 1885); "Notes on the Flora of Ceylon, with Descriptions of many new species" (*Journ. of Bot.*, 1885); "Hermann's Ceylon Herbarium and Linnæus's 'Flora Zeylonica,'" being a critical examination of the plants of Hermann described by Linnæus (Linn. Soc. Journ., 1887); "Report to the Madras Government on the Cinchona Plantations of that Presidency" (1883); "Annual Reports of the Botanic Gardens, Ceylon" (1880–85).

HENRY MARSHALL WARD, M.A.,

F.L.S. Fellow of Christ's College, Cambridge. Professor of Botany, Royal Indian Engineering College, Cooper's Hill (Forestry Branch.) Distinguished for his researches in Histological and Cryptogamic Botany. Appointed by the Secretary of State for the Colonies to visit Ceylon, 1879–81, to investigate the Coffee-Leaf Disease. Has published numerous researches, of which the following are the more important:—"On the Embryo-sac and Development of *Gymnodenia conopsea*" (*Quart. Journ. Micros. Sci.*, 1880, pls. 3); "A Contribution to our knowledge of the Embryo-sac in Angiosperms" (Journ. Linn. Soc., 1880, pls. 9); First, second, and third Reports on the Coffee-Leaf Disease, Ceylon, 1880–81 (*ibid.*); "Researches on the Morphology and Life-history of a tropical Pyrenomycetous Fungus (*Asterina*)" (*Quart. Journ. Micros. Sci.*, 1882, pls. 2); "Observations on the genus *Pythueni*" (*Quart. Journ. Micros. Sci.*, 1884, pls. 3); "On the Structure, Development, and Life-history of a tropical Epiphyllous Lichen (*Strigula complanata*)" (Trans. Linn. Soc., 1883, pls. 4); "On the Morphology and the Development of the Perithecium of *Meliola*, a genus of tropical Epiphyllous Fungi" (Phil. Trans., 1883, Pls. 3); "On the Structure and Life-history of *Entyloma Ranunculi*" (Phil. Trans. 1887, pls. 4); "On some points in the Histology and Physiology of the Fruits and Seeds of the genus *Rhamnus*" (*Annals of Botany*, 1887, pls. 2). Translator of "Lectures on the Physiology of Plants," by Julius von Sachs (Clarendon Press, 1887).

WILLIAM HENRY WHITE,

Assistant Controller and Director of Naval Construction. Charged with principal responsibility for design and construction of all ships of the Royal Navy. Author of a "Manual of Naval Architecture," adopted as a Text-book in the Royal Naval College, issued to the Royal Navy, translated into German and Italian, and officially issued to both fleets. Author of numerous papers on the science and practice of Shipbuilding, most of these being published in the Transactions of the Inst. of Naval Architects, of which he is a Member of Council. In these papers there is a large amount of original scientific work, notably in "Calculations for the Stability of Ships," 1871 (written jointly with Mr. M. John); The Geometry of Metacentric Diagrams," 1878; "The Rolling of Sailing Ships," 1881; "The Course of Study at the Roy. Nav. College," 1877. Engaged in extensive theoretical investigations and experiments on the Structural Strength of Ships, and the Strains to which they are subjected at sea. Many of the results published in the "Manual of Naval Architecture" and Trans. Inst. Nav. Architects. Has had much to do with the extension of systematic observations of rolling, pitching, and general behaviour of H.M. ships at sea, from which much good has resulted to Ship-design, and valuable additions have been made to trustworthy information on Ocean Waves. Has also been able to render good service to the general extension of scientific methods of observing and analyzing the steam trials and turning trials of H.M. ships. Was closely associated for some years with the late Mr. Froude, and with the practical development in the designs of H.M. ships of the principles deduced from model experiments originated and conducted by Mr. Froude, which experiments are now superintended by the late Mr. Froude's son, Mr. R. G. Froude. Is the designer of some of the swiftest ships afloat, both armoured and unarmoured, in which designs wide departures were made from previous practice. Is a member of the Inst. Civ. Eng.; of the Council of the Inst. Naval Architects; Hon. Mem. of the N.E. Coast Inst. of Engineers and Shipbuilders; Member of the Roy. Unit. Serv. Inst. Has diploma as Fellow of the Royal School of Naval Architecture (highest class). Professor of Naval Architecture at South Kensington, 1871–73, and at Royal Naval College, 1873–81.

THE ISLANDS OF VULCANO AND STROMBOLI.

IN the spring of last year, accompanied by my friend Signor Gaetano Platania, I passed a month in a geological ramble through the Æolian Islands. In consequence of such a short stay, no observations were carried out with sufficient detail and accuracy to be worthy of publishing, especially after the many important observations that we already possess from Spallanzani to Judd. Unfortunately, the isolated position of the group, and the absence of any sufficiently qualified local observer, render it impossible to have continuous records of the vulcanological and seismological phenomena of the islands; in fact, what little is known has come from the few scientific travellers who from time to time visit this out-of-the-way locality. It is for that reason, therefore, that the following notes have been written, in the hope of saving a few of the links in the broken chain of the record of the two active volcanoes of Stromboli and Vulcano.

We arrived at Vulcano on May 24, 1887, and left the island on May 28. The eruption that had occurred during February and two following months of 1886 had drilled out the bottom of the crater, so that the lower half of the path (on the west side) leading down to the bottom of the crater had been removed, and its lower end terminated abruptly in a cliff sheer down to the crater bottom. In consequence we were unable to descend, but we could on two days get a good view of the crater bottom. Much hissing and blowing off of steam was going on from the fissures of the floor of the crater, which was covered by a layer of purplish-gray ash washed down from the sloping sides. The edges of the fissures in the bottom and lower part of the crater sides were covered by a yellow crust of what was no doubt sulphur, boric acid, &c.

On the somewhat flattened ridge forming the northern lip of the crater, and not very far from the head of the celebrated obsidian lava stream, was a very large fumarole emitting a strong and large jet of steam under pressure, having about the size and force of that of the *bocca grande* of the Solfatara. With our sticks we removed some of the stones choking the hole, which on their cooler parts were covered with deposits of sulphur and realgar. When this was exposed to the full jet of steam, the minerals were melted, and blown away or over the surface of the blocks, forming a kind of reddish varnish or patina, whilst a rain of drops was thrown into the air, so that our clothes and hats were bespattered with beads of a variable mixture of sulphur and realgar. To the east side, where are distinguishable three crater rings, a considerable number of fumaroles exist, depositing chiefly sulphur, but also boric acid where hottest. Mr. Narlian, a resident in the island, says that not since the 1886 eruption "has the crater entered into its former quiescent condition."

On the upper portion of the northern slopes of the cone, to the east of the obsidian stream, all the ground is fumarolic, and choked with sulphur, where that mineral is extensively quarried.

Vulcanello seems on the verge of extinction, it being possible to find only slightly warm exhalations of watery vapour in a few fissures.

During the days we were at Vulcano we noticed that the apparent quantity of vapour emitted had a very marked relationship to the moisture of the atmosphere, and therefore, indirectly, to the winds. The same we also observed to be the case at Vulcano as we saw it from time to time during our stay on the Island of Lipari.

June 1, 2, and 3 were spent at Stromboli. In ascending the volcano, we, on leaving the town, skirted the northern coast of the island, and after passing the Punta Labronzo commenced the ascent, gradually approaching the north-east limit of the Sciarra. It is a track that passes chiefly over hard rock, and to be strongly recommended in preference to any other paths, which are mostly over loose materials. Skirting the crater, one walks along the ridge of the mountain which overhangs and partly hides the crater; we commenced to descend a little on the south side of the volcanic mouth, until we arrived at a small pinnacle of rock, where a good view of the crater was obtainable. Here, under very great difficulties, from the looseness of the ground of about two square metres upon which we stood, an attempt was made to take two instantaneous photographs of the crater as we looked down into it. Unfortunately, both of these were useless, as we foresaw, from the vapour blowing towards us.

The crater was very quiet, only throwing out a very few fragments of pasty lava cake, with about four or five explosions during the four hours we remained near by. There were other explosions, but too weak to eject anything. I descended to the crater edge, but could not remain long, on account of the heat of the ground and the acid fumes, which seemed to be in great part composed of HCl with a good dash of SO_2.

On returning from the crater edge and descending a little lower on the south-west of the Sciarra, a good view is obtainable of that slope and the crater. Here two successful photographs were taken, which show very well the crater with its relative position to the summit of the mountain and to the Sciarra. On the following day the tour of the island was made in a boat, and, as only a few stones were being ejected, we were able to land on the narrow ledge or beach at the foot of the Sciarra. Two successful photographs were taken from the Scoglio dei Cavassi, from which a fine view is obtainable of the Sciarra and the crater.

During our residence on the island, and our stay at Salina and Panaria, we always noticed that the amount of visible vapour issuing was in direct proportion to the humidity of the atmosphere. On account of the great quietness of the volcano, it was impossible to form any judgment as to whether there was any relation of increased or diminished activity to the barometric pressure, and so, indirectly, to the winds.

Since leaving the island, correspondence has been kept up between Signor Giuseppe Rende, the post and telegraph master, and myself. The following information I have been able to glean from that gentleman's letters. From June to November 1887 the volcano remained in its normal state. On November 18, a moderate eruption (*eruzione mediocre*), and the wind blowing from the west, a shower of scoria (? fragments) (*aride pietre*), fell amongst the vines near the village. This was accompanied by explosions (*botti*), which, it appears, considerably frightened the people. Later, the scoria (*pomice*) fell into the sea, which it covered as far as the eye could see. Unfortunately, Signor Rende did not preserve any of the *ejectamenta*, but, judging from what one sees composing recent deposits of the island, the material was a pumiceous scoria, or a light scoria, as it appears to have floated on the sea.

In answer to further inquiries, Signor G. Rende tells me that the floating scoria extended *eastwards* as far as the eye could reach. No lava appeared, but a small mouth opened at the edge of the crater, but in a very few days disappeared. He then goes on to say :—

"I draw your attention in this letter to a very remarkable fact. On the 25th of last February (*i.e.* 1888), at 4.21 p.m., occurred two little shocks of earthquake of *undulatory* character, followed by a *subsultory* one, so that we thought it would be the end of the world for us. Never had a *subsultory* earthquake been felt. It split various houses, overturned walls, and made earth-banks slip. Those who had their eyes fixed on the mountain seemed to see the summit of it fall over from south to north. People who were working amongst the vines fell on their faces. No victims. Neither Panaria, Lipari, nor the other islands noticed the shock. The volcano (*i.e.* Stromboli) was in no way affected (*non fece mossa alcuna*)."

Prof. Mercalli has collected together what is known of the history of Vulcano and Stromboli. He also published accounts of the state of these volcanoes during the years 1882–86 inclusive ("Natura delle eruzione dello Stromboli," *Atti della Soc. Ital. di Sc. Nat.* vol. xxiv.; "Notizie sullo stato attuale dei vulcani attivi Italiani," *ibid.* vol. xxvii.; "La fossa di Vulcano e lo Stromboli dal 1884 al 1886," *ibid.* vol. xxix.).

The eruption of November 18, 1887, is curiously near the date of November 17, 1882, when one of the strongest modern eruptions of Stromboli occurred, and when five lateral mouths opened on the Sciarra about 100 metres below the crater edge, but without the ejection of a lava stream. As on one or two other occasions, the last eruption extensively covered the sea with scoria, a fact of no small importance when we take into consideration that Stromboli is a very basic volcano, in a unique state of chronic activity, and is yet able to produce scoria or pumiceous scoria, sufficiently vesicular to float on the sea, and so be transported to great distances.

With regard to the position of lateral eruptions of this mountain, the only situation in which dykes are visible is on the north-west side and near the Sciarra, where a considerable number are to be seen. One of these is visible in section near La Serra, showing it continuous with a lava flow that oozed from it only a few metres above sea-level, indicating that not very long since a lateral eruption gave rise to a lava stream; another, close to the crater, stands out as a great wall at right angles to the present eruptive axis of Stromboli, and certainly must have been formed when the crater was at a very much higher level. No less than three dykes at Stromboli are *hollow* ones, with their interspace filled in from above by loose materials, showing that they must also have been drained below present sea-level, as they reach—as hollow dykes—down to the beach. I believe I was the first to draw attention to this peculiar variety of dyke, in describing the eruption of Vesuvius of May 2, 1885, where it was possible to watch the process of formation ("L'Eruzione del Vesuvio nel 2 Maggio, 1885," *Ann. d. Accad. O. Costa d'Asp. Naturalisti*, Era 3, vol. i.; and "Lo Spettatore del Vesuvio," Napoli, 1887). These hollow dykes of Stromboli may be seen at La Serra, the northern limit of La Sciarra, and at Punta Labronzo. I expected them to be rare, as there is no mention of them made in any literature known to me; but as it is also well shown near the Punta del Corno, at Vulcano, it can hardly be the case.

In conclusion, I take this opportunity of thanking Signor Narlian, of Vulcano, and Signor Rende for their past kindness, and for the promise of further notes on these two isolated, neglected, but interesting volcanoes.

H. J. JOHNSTON LAVIS.

HEAD GROWTH IN STUDENTS AT THE UNIVERSITY OF CAMBRIDGE.[1]

IN the memoir read by Dr. Venn, on April 24, at the Anthropological Institute, upon the measurements made, during the last three years, of the students of Cambridge, one column is assigned to what he terms "Head Products," and which may fairly be interpreted as "Relative Brain Volumes." The entries in it are obtained by multiplying together the maximum length and breadth of the head and its height above a specified plane. The product of the three determines the contents of a rectangular box that would just include the portion of the head referred to. The capacity of this box would be only rudely proportionate to that of the skull in individual cases, but ought to be closely proportionate in the average of many cases. The relation they bear to one another affords, as it seems to me, a trustworthy basis for the following discussion, especially as all the measurements were made not only on a uniform plan, but by the same operator.

[1] Read at the Anthropological Institute, on April 24, by Francis Galton, F.R.S.

It will be convenient to reproduce Dr. Venn's figures in a separate table, neglecting the second decimal:—

Head Products.

Ages.	Class A. "High honour" men.	Number of measures.	Class B. The remaining "honour" men.	Number of measures.	Class C. "Poll" men.	Number of measures.
19	241·9	17	237·1	70	229·1	52
20	244·2	54	237·9	149	235·1	102
21	241·0	52	236·4	117	240·2	79
22	248·1	50	241·7	73	240·0	66
23	244·6	27	239·0	33	235·0	23
24	245·8	25	251·2	14	244·4	13
25 and upwards.	248·9	33	239·1	20	243·5	26
		258		476		361

The figures in the table are thrown into diagrams in Figs. I., II., and III., in which curves are also drawn to interpret what seems to be their significance. The great irregularity in Fig. II., corresponding to the age of twenty-four, may be fairly ascribed to the smallness of observations, only thirteen in number, on which it is founded. The three resultant curves are shown by themselves in Fig. IV., where they can be easily compared. It will then be seen that the A and C curves are markedly different, and that the B curve is intermediate. Accepting these curves as a true statement of the case—and they are beyond doubt an approximately true statement—we find that a "high honour" man possesses at the age of nineteen a distinctly larger brain than a "poll" man in the proportion of 241 to 230·5, or one that is almost 5 per cent. larger. By the end of his College career, the brain of the "high honour" man has increased from 241 to 249; that is by 3 per cent. of its size, while the brain of the "poll" man has increased from 230·5 to 244·5, or 6 per cent.

Four conclusions follow from all this:—

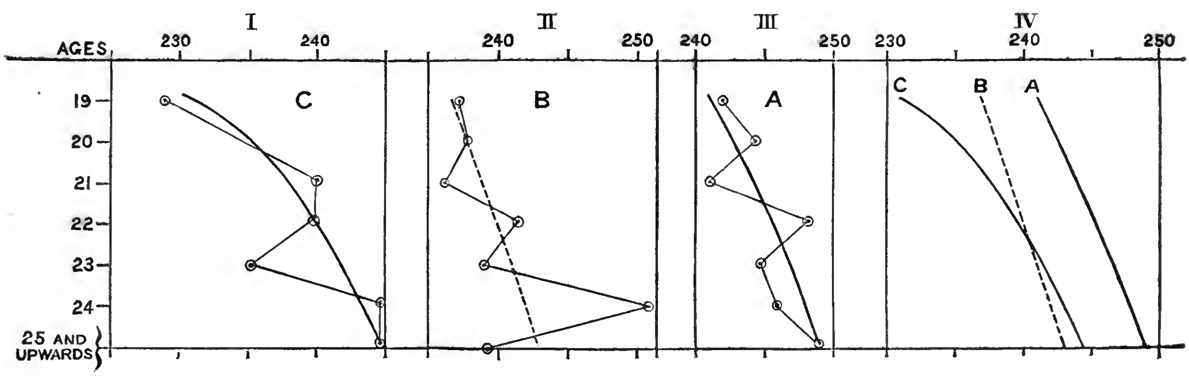
(1) Although it is pretty well ascertained that in the masses of the population the brain ceases to grow after the age of nineteen, or even earlier, it is by no means so with University students.

(2) That men who obtain high honours have had considerably larger brains than others at the age of nineteen.

(3) That they have larger brains than others, but not to the same extent, at the age of twenty-five; in fact their predominance is by that time diminished to one-half of what it was.

(4) Consequently "high honour" men are presumably, as a class, both more precocious and more gifted throughout than others. We must therefore look upon eminent University success as a fortunate combination of these two helpful conditions.

Length × Breadth × Height of Head, in inches, of Cambridge University Men at different Ages (from Dr. Venn's Tables).



A, First Class Men; B, Honour Men, not First Class; C, Poll Men.

PHOTOGRAPH OF THE EYE BY FLASH OF MAGNESIUM.

THE effect of complete obscurity on the normal pupil has hitherto been seen only by the light of electric discharges, which allowed of no measurements.

MM. Miethe and Gaedicke, by their invention of the well-known explosive magnesium mixture, have furnished us with a simpler method. A photograph of the eye can be taken in a perfectly dark room, showing the pupil fully dilated, as its reaction does not begin until after exposure.

Mr. Miethe, astronomer at the Potsdam Observatory, himself at my suggestion undertook to execute the accompanying photograph of a normal eye, life-size, after a quarter of an hour's rest in a carefully darkened room. The pupil was found to measure 10 mm. horizontally (the breadth of the cornea being 13 mm.). A reflection of the flash is seen on the cornea.

This kind of photography may prove a new and valuable method for many other branches of scientific

research, but it is of especial utility to ophthalmology, as the eye, by its mobility and sensitiveness, has hitherto been a most difficult subject for the camera.

CLAUDE DU BOIS-REYMOND.

NOTES.

THE Council of the British Association has nominated Prof. Flower for the Presidency of the meeting to be held next year at Newcastle.

THE annual *conversazione* of the Royal Society will be held on Wednesday, May 9.

THE Council of the Marine Biological Association has appointed Mr. Gilbert C. Bourne, M.A., F.L.S., Fellow of New College, Oxford, to be Director and Secretary of the Plymouth Laboratory. Mr. Bourne began the study of biology under Dr. P. Herbert Carpenter at Eton College, and in 1881 obtained an exhibition in natural science at New College. After studying under Prof. Moseley at Oxford and Prof. Aug. Weismann at Freiburg in Baden, Mr. Bourne was placed in the first class in the honour school of natural science at Oxford in 1885. Immediately after taking his degree he proceeded to Diego Garcia in the Indian Ocean, with the purpose of investigating the fauna and flora of that island. On his return to England he became assistant to Prof. Moseley at Oxford, and has performed the duties of Lecturer and Demonstrator in Animal Morphology for the last two years. In October last Mr. Bourne was elected to an open Fellowship at New College.

ON the evening of April 5, about one hundred and fifty persons interested in science met in the hall of the Columbian University, Washington, to pay a tribute to the memory of Asa Gray. Prof. Langley, Secretary of the Smithsonian Institution, presided, and addresses were delivered by Prof. Chickering, Dr. Vasey, Prof. L. F. Ward, and Dr. C. V. Riley.

THE sixty-first meeting of the German Association of Naturalists will take place at Cologne from the 18th to the 23rd of September next. Prof. Bardenheuer and the chemist Th. Kyll are the secretaries. The subjects to be considered will be divided into thirty sections.

THE following sums for the furtherance of scientific studies have been presented by the Academy of Sciences at Berlin: 1500 marks (£75,) to Dr. Goldstein (Berlin), a physicist; 2000 marks (£100) to Dr. Fabricius (Berlin), the archæologist, and Dr. Suhlmann (Würzburg); and 900 marks (£45) to Prof. Gerhard (Eisleben).

CAPTAIN C. E. DUTTON, of the U.S. Geological Survey, is writing his monograph on the Charleston earthquake. The reports on which it will be based are complete, and in shape for the printer. *Science* is of opinion that no earthquake of ancient or modern times has been observed with such care and fulness of detail. Besides the observations made by Professors in several Colleges, by hundreds of railway officials, and at signal stations, a large number of intelligent private citizens have given an account of their own experiences. The volume which Mr. Dutton is editing will also contain a report on the Sonora earthquake.

ON the night of April 17 a magnificent display of the aurora borealis was observed at Motala, in Sweden, in the northern sky. On the same night at 9.5 p.m. a phenomenon was seen in the north-western sky at Örebro, also in Central Sweden, having the appearance of a bright horizontal flash of lightning, but without any report. It was followed by the appearance of an unsteady and varying aurora. The thermometer stood at 21° C.

ON the night of March 27 a rumbling noise like that of a distant earthquake was heard at Aaseral, in Southern Norway, but no shock was felt. It could not have been thunder, as the weather was clear and intensely cold.

ACCORDING to the official report of the recent great earthquake in Yunnan Province of China, the shocks commenced between 5 and 6 p.m. on January 14, and lasted till 4 o'clock the following morning. During this period about ten serious shocks were counted, all being accompanied by a noise like thunder. In district cities in the south of the province, the town walls were either thrown down or cracked, while public offices and temples shared the same fate. In the city of Shih-ping large numbers of private houses were destroyed, those in the south and east quarters suffering most, while those which remained standing had cracked or slanting walls. Two hundred persons were killed in this town alone, and 3000 were injured. In and around this single city about 5000 persons were killed and injured. Most of the people were left without homes, and were starving, as the provisions were buried in the ruins of the houses. In one town the gaol was thrown down by the shocks, and all the prisoners escaped. The earthquake is said to be the most destructive ever recorded in China. The locality in which it was most violent is mountainous, and produces copper and a particular kind of tea for which Yunnan is famous. The area of disturbance is said to be about 770 miles from east to west, and 60 from north to south, Shih-ping being near the centre. The direction of the shocks appears to have been at right angles to the prevailing direction of the valleys, lakes, and rivers of the region. This, at least, is how the Pekin correspondent of a Shanghai newspaper reads the report; and he adds that from the centre of intensity, a little to the west of the city of Shih-ping, there was a decided extension of the earthquake-wave northward in the direction of the Yunnan lake Tienchih, as well as westward to the city of Weiyuen.

IT is curious to notice that on the day when this earthquake occurred there was one also at Luchon, a town in the Szechuen Province, about 350 English miles north-east of the locality of the Yunnan earthquake. Much loss of life is said to have taken place here also, and there was a great subsidence of land. No official report respecting this second earthquake has yet made its appearance.

THE Manilla Government has intrusted to the Sub-Director of the local Observatory the task of studying the causes of the numerous storms which prevail along the coast of the Philippine Archipelago as well as inland, with a view to drawing a meteorological chart of the islands, and of establishing their magnetic positions.

THE Pilot Chart of the North Atlantic Ocean for the month of March, issued by the United States Hydrographer, contains the following interesting facts. Three pronounced cyclonic storms passed over the North Atlantic during the month. One of these was in some respects one of the most remarkable and destructive storms ever experienced along the Atlantic coast of the United States. After traversing the entire American continent from west to east without any noteworthy energy, it gained terrific force on reaching the coast to the southward of Hatteras on the 11th. Its progress eastward was delayed from the 11th to the 15th by an area of high barometer, and it then resumed its course easterly with renewed energy, crossing the 40th meridian in about 50° N. latitude. Much less fog was experienced off the Grand Banks than usual during March. Field ice was encountered as far south as 43° N., and between 46° and 60° W., but the amount reported was not great. Earthquakes were experienced by the United States store-ship at Coquimbo on January 4, and by the British ship *Diadem* in latitude 26° 2′ N., longitude 63° 19′ W., on March 1. The sensation in the latter case was as though the vessel had grounded upon a reef.

IN the storm to which reference is made in the preceding note, oil seems to have been freely used off the coast of the United States for the calming of the waves. According to *Science*, more than a dozen captains and sailing-masters caught in the tempest when at its worst believe their vessels were saved by this expedient. The sailing-master of the yacht *Iroquois* reports that when furious waves with an immense comb were approaching they were deprived of their power to do harm by "a patch of oil no larger than a dining-room table."

ANOTHER interesting mineral synthesis has just been effected by M. Dufet. Native di-calcium arsenate, pharmacolite, occurs very sparingly upon the known parts of the surface of our globe, and is so rarely found in well-defined crystals that M. Des Cloizeaux has only just completed his investigation of its mineralogical and optical properties. Generally it is found in the form of silky fibres, but is at times met with in perfect monoclinic prisms of pearly lustre and frequently possessing a pink tint. M. Dufet has succeeded in producing these beautiful crystals by a very ingenious method. Two concentric vases, the outer containing nitrate of lime and the inner di-sodium arsenate, were filled with water, and so arranged that very slow diffusion occurred between the two liquids. The conditions of Nature were evidently very closely imitated, for the very gradual precipitation thus brought about resulted in the formation of groups of crystals, exactly resembling those of pharmacolite. Goniometrical measurements showed that they belonged to the monoclinic system; and the close approximation of the fundamental angles to those of the mineral given by Haidinger and Schrauf, and especially the still more remarkable closeness to the values just arrived at by M. Des Cloizeaux, leave no doubt as to the identity of the artificial with the natural. The chemical analysis of M. Dufet's crystals leads to the formula $HCaAsO_4 + 2H_2O$, and it thus becomes chemically as well as physically isomorphous with brushite, the corresponding phosphate of calcium, $HCaPO_4 + 2H_2O$. This result clears up the discrepancy between the acknowledged formula of the latter mineral and that given by older mineralogists for pharmacolite, $2HCaAsO_4 + 5H_2O$. The number of minerals which have now been reproduced in the laboratory must be very considerable, and every day the likelihood is increasing that those noble species which have for ages been prized as gems may discover the secret of their formation to some indefatigable worker. Rubies and sapphires have already yielded, possibly the diamond may not prove refractory much longer.

A VALUABLE paper, describing a new method of extraction of the alkaloids from Cinchona bark by cold oil, as used at the Government Cinchona Factory in Sikkim, was lately drawn up by order of the Lieutenant-Governor of Bengal, and has now been issued. Dr. King, the Superintendent of the Sikkim Plantation, carried on a long series of experiments on an acid and alkali process of manufacture, by which he succeeded in producing an excellent quinine. He never, however, succeeded in recovering much more than half of the amount contained in the bark on which he operated. The acid and alkali process had, therefore, to be abandoned, as wasteful and inefficient. A process depending on the maceration of the bark in spirit was next tried, but, after much experiment, it was in turn abandoned. During a visit which Dr. King paid to Holland in 1884, he obtained some hints as to a process of extraction by means of oil. Benefiting by the advice of some chemical friends, Mr. Gammie, the resident manager in Sikkim, has been able to perfect this process, with the result that the whole of the quinine in yellow bark can be extracted in a form indistinguishable, either chemically or physically, from the best brands of European manufacture. This can be done cheaply, and the Bengal Government has caused an account of the matter to be printed, in order that private growers of Cinchona may be enabled to take full advantage of the process, and that a permanent reduction in the price of quinine may ensue.

THE Trustees of the Indian Museum, Calcutta, have issued a circular announcing that they have had under their consideration the means whereby a useful scientific examination of the insect-pests of India can be best effected. Bearing in view the great economic importance of the investigation, they have directed the first assistant, Mr. E. C. Cotes, to consider it an essential portion of his duties, and have instructed him to communicate with persons interested in the subject, and likely to aid the inquiry, in order to collect materials which may form a sufficient basis for really scientific conclusions. Mr. Cotes will gradually record the entire life-histories and practical methods of dealing with the principal insect-pests, publishing from time to time, as materials accumulate, the information collected, and distributing it to those interested. Those who live in the districts where the insects occur, and have actual experience of the pests, are invited to send to Mr. Cotes accounts of facts they have observed; and the circular includes a full statement of the points upon which information is wanted.

READERS interested in the science and practice of forestry will be interested in the perusal of a Report by the American Consul at Mayence, on Forest-Culture in Hesse, contained in the January issue of the Consular Reports of the United States. The writer discusses the organizations and functions of the department having the care of forests, the duties of the various classes of officials employed in forest-cultivation, the economical results of the system pursued, the course of instruction followed in the schools of forestry, the organization and methods of the institution for experimental forestry, and the degree and amount of control assumed by the State over private forests. The Report is exceedingly detailed, and is practically a handbook of forestry as practised in the Grand Duchy.

PROF. BLANCHARD, the well-known entomologist, has just published in Paris a book on "La Vie chez les Êtres animés," in which he discusses Darwinism at length, but in a very incomplete manner, and of course in a hostile spirit.

THE address delivered by Mr. A. D. Michael, President of the Quekett Microscopical Club, on the 24th of February last, is printed in the Club's Journal, and has also been issued separately. The subject is "Parasitism."

PROF. HENRY DRUMMOND has in the press a new book, "Tropical Africa," which will be published immediately by Messrs. Hodder and Stoughton. It will contain an account of the author's recent travels in Central Africa, with one or two chapters of natural history.

MR. LEWIS, of Gower Street, will publish immediately a volume of "Physiological and Pathological Researches," by the late T. R. Lewis, F.R.S. (elect). The work is edited by Sir William Aitken, F.R.S., G. E. Dobson, F.R.S., and A. E. Brown, and contains five maps, forty-three plates, including chromo-lithographs, and sixty seven wood engravings.

AT the meeting of the Institution of Civil Engineers on Tuesday, April 24, Mr. E. B. Ellington read a paper on the distribution of hydraulic power in London. In the course of his remarks he took occasion to refer to the large extent to which lifts are now used, and he considered it necessary, he said, to urge the importance of securing the greatest possible safety in their construction by the general adoption of the simple ram. Suspended lifts depended on the sound condition of the ropes or chains from which the cages hung. As they became worn and untrustworthy after a short period, it was usual to add safety appliances to stop the fall of the cage in case of breakage of the suspending ropes, but these appliances could not be expected to act under all circumstances.

MISS MARIE BROWN, well known for her researches on the earliest colonization of North America by the Scandinavians, has presented a petition to the United States Congress urging that steps should be taken to secure a thorough search of the

Vatican and other Italian libraries with a view to further light being thrown upon this question.

MR. W. CHANDLER ROBERTS-AUSTEN will give the discourse on Friday evening, May 11, at the Royal Institution in place of Mr. W. H. Barlow, who is unwell.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♀), from India, presented by Mr. Lionel H. Hanbury; a Macaque Monkey (*Macacus cynomolgus* ♂), from Burma, presented by Mrs. G. E. Buchanan; a Scarlet Ibis (*Eudocimus ruber*), a Roseate Spoonbill (*Platalea ajaja*), from Brazil, presented by Mr. Charles Booth; a Common Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. H. Weetman, F.Z.S.; a Hoffmann's Sloth (*Cholopus hoffmanni*), from Panama, deposited; three Lined Finches (*Spermophila lineola*), from South America, purchased; two Persian Gazelles (*Gazella subgutterosa* ♂ ♀), two Chinchillas (*Chinchilla lanigera*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *MAY* 6–12.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 6

Sun rises, 4h. 24m.; souths, 11h. 56m. 25·9s.; sets, 19h. 29m.: right asc. on meridian, 2h. 55·5m.; decl. 16° 44′ N. Sidereal Time at Sunset, 10h. 29m.

Moon (New on May 11, 1h.) rises, 3h. 15m.; souths, 8h. 49m.; sets, 14h. 34m.: right asc. on meridian, 23h. 47·5m.; decl. 5° 36′ S.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. on meridian. h. m.	Declination on meridian. ° ′

GEOGRAPHICAL NOTES.

THE *Mouvement Géographique* contains details of Lieut. Van Gèle's recent exploration of the River Mobangi, the great tributary of the north bank of the Congo, which discharges a little below the equator. It will be remembered that the Rev. George Grenfell succeeded in making his way up the river as far as 4° N. latitude, where he was stopped by the Zongo rapids. Lieut. Van Gèle started on October 26 last, and reached the rapids on November 21. There are six of them, covering a space of 34 miles. They are situated in what is really a mountain gorge, the mountains, in gentle slopes, coming down to the river banks. The steamer *En Avant* had to be unloaded several times and dragged up the rapids. The spaces between the rapids are mostly covered with islands, with great bars of rock stretching between them. The country on each side is described as being fine, fertile, and covered with villages. The people here are all of the same tribe; head shaved except at the nape, bristling moustaches, and no tattooing. Above the middle falls, the Bakombé inhabit the country. These arrange the hair in *queues*, some of which are over 6 feet long. From the upper end of the falls the river continues in a north-east direction for about 32 miles, when it rounds to the east. It has a breadth of about 2600 feet, and the navigation is easy, the average depth being 14 feet. The easterly direction is maintained as far as the *En Avant* went, about 172 miles further. The mountains disappear from the right bank, and the left is marked by low hills, with grassy plains and woods alternating. The villages are at some distance from the river, but the people came down to the vessel in crowds all the way up, and were perfectly friendly until the last few days. Over the whole course tropical cultures of every kind were abundant, as well as sheep, goats, and fowls. The natives on the right bank belong to the Buraka and Maduru tribes; those on the right to the Bakangi, the Mombate, and the Banzy. They mostly shave the head so as to leave a triangle of hair, with the forehead as base. The ears are enormously elongated with heavy copper rings. The river here is covered with islands, mostly cultivated and inhabited. Among the Banzy the huts have the shape of huge conical extinguishers, resting on a circular wall about 2 feet high. These huts are ranged in circular rows, forming broad streets, well kept, and with a common meeting-house in the centre. Each hut is divided into two apartments, one used for sleeping. Iron is admirably worked into all sorts of implements, weapons, and ornaments. Ivory is abundant, but used only for bracelets, anklets, and *pelelé* or lip-ornaments. About 100 miles above the Zongo rapids a second is met with, at Bemay. The vessel succeeded in passing it, and a third 25 miles further up. Just above Bemay, the only tributary met with from the Zongo rapids upwards—the Bangasso—discharges into the right bank of the Mobangi. Above the river the country is densely peopled by the Mombongo and Yakoma, and these showed themselves distinctly hostile to the expedition. There were unfortunately several conflicts, in which lives were lost on both sides. Rocks and sand-banks obstructed the navigation, and after getting as far as 21° 55′ E., Lieut. Van Gèle turned back, making his way downwards with some difficulty, as the river had lowered about 10 feet. He arrived at Equator Station on February 1. The river was about 8000 feet wide at the furthest point, and covered with islands, mostly inhabited. On the north bank of the river, one village extended along a distance of 3 miles. As Dr. Junker's furthest point on the Wellé was 22° 55′ E., only 1° of longitude separates his point from Van Gèle's furthest, or about 68 miles. As they are both on the same line of latitude, there can be no doubt that the Mobangi and the Wellé are the same river.

FROM an official Report by Mr. Percy Smith, Assistant Surveyor-General of New Zealand, on a visit to the Kermadec Islands, in August last, we glean some information as to this recent annexation to the British dominions. The group is situated between the parallels of 29° 10′ and 31° 10′ S. lat., and between the meridian of 177° 45′ and 179° W. long. There are four islands, with some outlying isiets and rocks, the most northerly, Raoul or Sunday Island, being 674 miles north-east of Auckland. The islands are all volcanic; in two of them, indeed, signs of volcanic activity are to be seen at the present day, though on a limited scale. They appear to be situated on an oceanic plateau which extends from New Zealand to the Tonga Group, on which soundings are obtained at depths much less than in the adjacent areas, but still so great as to show that the islands form, as it were, the tops of volcanic cones rising to a great height above their bases. The group is situated on the north-easterly projection of the axis of the volcanic zone of the Bay of Plenty, which, continued still further north-eastward, strikes the Tonga and Samoan Groups, places where volcanic action is still going on. Two, if not three, volcanic disturbances have taken place at the Kermadec Islands within recent years, and earthquakes were very frequent there at one time; but since the eruption of Tarawera, June 10, 1886, they have ceased entirely. On Sunday Island the most prominent feature is the large crater near the centre of the island. It is $1\frac{3}{4}$ mile long by $1\frac{1}{4}$ mile wide; its walls are generally over 1000 feet high. Steam escapes occasionally from the Green Lake on the south side, and from the crevices in the precipitous cliffs of Denham Bay, while warm water oozes out of the sand on the north coast.

DR. HANS MEYER, who recently ascended Kilimanjaro, and Dr. O. Baumann, who accompanied Dr. Lenz up the Congo, are preparing to start on a new expedition to East Africa. Their object will be to make a thorough exploration and survey of the whole of the Kilimanjaro region.

RECENT issues of the journals published in French Indo-China, contain an interesting letter from M. Gauthier, describing a journey down the Meikong River, from Luang Prabang into Cambodia. The traveller spent forty days on the journey, and passed twenty cataracts, in one of which his boat was almost dashed to pieces. He visited the Laos States, and describes its inhabitants as doing nothing except laughing, smoking, and singing throughout the day, such business as there is being wholly in the hands of the Chinese.

OUR ELECTRICAL COLUMN.

GOUY has found that the attraction between two electrified surfaces maintained at a constant potential-difference is one hundred times greater in distilled water than in air.

ADMIRABLY well-equipped public electrical laboratories have been established in Paris and Vienna. When are we to see one in London?

VAN AUBEL (*Arch. de Genève*, xix. p. 105, 1888) has been studying the effect of magnetism and heat on the electric resistance of bismuth and of its alloys with lead and tin. Contrary to all other metals, the resistance of bismuth sometimes increases with reduction of temperature. He also verified the fact that the resistance of bismuth at low temperatures increases in the magnetic field. The effect is very feeble with alloys.

FOEPPL (*Ann. Wiedemann*, xxxiii. p. 492) has been endeavouring to prove Edlund's hypothesis that a perfect vacuum is a conductor, but has completely failed to do so. He makes the resistance of a vacuum to be three million times greater than that of copper.

MR. C. VERNON BOYS has communicated to the Royal Society some further details of his beautiful radio-micrometer. It is a thermo-electric circuit, consisting of a bar of antimony and bismuth, of small sectional area, the ends being formed by a loop of copper wire, suspended by a torsion fibre in a strong magnetic field. It is possible to observe by its means a difference of temperature of one ten-millionth of a degree Centigrade.

C. L. WEBER (*Centralblatt für Elektrotechnik*, 1887, vol. ix.), experimenting on various amalgams and alloys of tin, bismuth, lead, and cadmium, has found that many of them have a higher conductivity than that of each of their constituents.

SIRKS, of Deventer (Holland), has found a peculiar dynamical action of the current on the electrodes. An electrical current passing through a solution of $CuSO_4$ between two electrodes of copper, which are varnished at the back, pulls *both against* the direction of the positive stream. Independently of the concentration, if only high enough to prevent the formation of gases, the pressure at the anode and the traction at the kathode amount to nearly 1 gramme per ampere and per square metre.

ON THE COMPARISON OF THE CRANIAL WITH THE SPINAL NERVES.

THE origin of vertebrate animals is to be found according to many morphologists in those invertebrates which are composed of a series of segments, and one of the chief arguments in favour of this view has always been the fact that the spinal nerves are arranged segmentally. It has, however, long been felt that the cranial nerves ought to give evidence of a segmental arrangement as clearly as the spinal before it is possible to speak of a segmentation based upon the arrangement of the nervous system; and indeed many ingenious tables have been manufactured by morphologists in order to bring the cranial nerves into the same system as the spinal. The failure of these attempts is to my mind due largely to the following reasons:—

1. Confusion has arisen because anatomists have been in the habit of looking upon the nervous system of the vertebrate as composed of two separate nervous systems, viz. the cerebro-spinal and sympathetic.

2. In the comparison of cranial and spinal nerves the morphologists have directed their attention too exclusively to the exits of the nerves from the central nervous system without taking into account the place of origin of the nerves in the central nervous system itself.

3. It has been assumed on insufficient grounds that the presence of ganglia in connection with motor cranial nerves indicates that the cranial nerves do not follow Bell's law, and are therefore not strictly comparable with spinal nerves.

These difficulties are all found to vanish as soon as a clear conception is obtained of what is meant by the nerves of a spinal segment.

Since the time of Charles Bell it has been recognized that a spinal nerve is formed by two roots: the one, posterior, which contains only afferent fibres, *i.e.* fibres which convey impulses from the periphery to the central nervous system; and the other, anterior, containing exclusively efferent fibres which convey impulses from the central nervous system to the periphery. In correspondence with these two sets of fibres the grey matter of the spinal cord is divided into two portions, named respectively ths posterior and anterior horns. Another division, however, exists of almost equal importance, which is not so generally recognized, viz. a division both of the nerve fibres and their centres of origin in the grey matter for the purpose of supplying the internal and external portions of the body—a division of nerves and nerve centres into splanchnic and somatic as well as into afferent and efferent. The centres of origin of the splanchnic nerves are situated in the internal part of the grey matter of the spinal cord, being arranged in groups in the neighbourhood of the central canal, and the nerves themselves supply the viscera and internal surfaces of the body, together with certain muscles of respiration and deglutition which are derived from special embryonic structures known as the lateral plates of mesoblast. On the other hand, the centres of origin of the somatic nerves are situated in the outlying horns of grey matter, and the nerves themselves supply the integument and the ordinary muscles of locomotion, &c.,—muscles which are derived from the muscle-plates or myotomes.

Further, these two sets of nerves are arranged in the posterior and anterior roots in a special manner, the significance of which is the key to the whole question of the segmental nature of the cranial nerves. In the posterior roots the afferent fibres of both splanchnic and somatic systems pass into the spinal ganglion, which is always situated on the nerve root soon after its exit from the central nervous system; so that we may speak of the afferent fibres of both systems as being in connection with a ganglion which is stationary in position. In the anterior roots, on the other hand, we find that some of the fibres are in connection with no ganglia, while others are in connection with ganglia which are not fixed in position, but are found at various distances from the central nervous system (it is this system of ganglia which has hitherto been looked upon as forming a separate nervous system, viz. the sympathetic system), so that the fibres of the anterior root, all of which are efferent, are divisible into a ganglionated and a non-ganglionated group, of which the ganglionated group belongs to the splanchnic system, and is characterized by the smallness in the size of its fibres, while the non-ganglionated group is composed both of somatic and splanchnic nerves, and forms the ordinary large-sized motor nerve fibres of the voluntary striped muscles both of respiration and deglutition as well as of locomotion.

Again, it has been shown that these efferent ganglia are in reality offshoots from a primitive ganglion mass situated on the spinal nerves into which both afferent and efferent fibres ran.

We see, then, that both roots of a fully formed spinal nerve are ganglionated, so that the presence of a ganglion is no longer the sign of a posterior root, and we must define a spinal nerve as being formed by—

1. A posterior root, the ganglion of which is stationary in position and is connected with both splanchnic and somatic afferent nerves.

2. An anterior root, the ganglion of which is vagrant, and is connected with the efferent small-fibred splanchnic nerves.

Also it is not a fundamental characteristic of a spinal nerve that the anterior root should necessarily pass free from the spinal ganglion, for it is clear that both anterior and posterior roots may pass into the same stationary ganglionic mass if the whole or part of the efferent ganglion has not travelled away from the parent mass. This passage of the fibres of the anterior as well as of the posterior roots into the spinal ganglion is common enough in the lower animals, and is a peculiarity of the first two cervical nerves in such an animal as the dog. If, then, the cranial nerves are formed on the same plan as the spinal, their efferent roots ought to be divisible into a large-fibred non-ganglionated portion and a small-fibred ganglionated portion, the ganglia of which may be vagrant in character, while their afferent roots should possess stationary ganglia near their exits from the brain; also the centres of origin for the different sets of nerve fibres, *i.e.* for the splanchnic and somatic nerves, ought to be the direct continuation of the corresponding centres of origin in the spinal cord. Such I find to be the case; if we leave out of consideration the nerves of special sense, viz. the optic, olfactory, and auditory nerves, the remaining cranial nerves are found to divide themselves into two groups—

(1) A foremost group of nerves, which in man are entirely efferent, viz. third, fourth, motor part of fifth, sixth, and seventh nerves.

(2) A hindmost group of nerves of mixed character, viz. ninth, tenth, eleventh, and twelfth nerves, and the sensory part of fifth.

The nerves of the first group resemble the spinal nerves as far as their anterior roots are concerned, for they are composed of large-fibred non-ganglionated motor nerves and small-fibred splanchnic efferent nerves, which possess vagrant ganglia, such as the ganglion oculomotorii, the ganglion geniculatum, &c.

They resemble spinal nerves also as far as their posterior roots are concerned, for they have formed upon them a ganglion at their exit from the brain corresponding strictly to the stationary posterior root ganglion of a spinal nerve. One great difference, however, exists between their posterior roots and those of a spinal nerve, for neither the nerve fibres nor the ganglion cells of these roots are any longer functional; they exist simply in the roots of this group of cranial nerves in man, and other warm-blooded animals, as the phylogenetically degenerated remnants of what were in ages long since past doubtless functional ganglia and functional nerve fibres.

This foremost group of cranial nerves, then, is built up on precisely the same plan as the spinal nerves; the apparent difference being due to the fact that the afferent roots with their ganglia have degenerated.

The hindmost group of cranial nerves is also composed of the same constituents as the spinal nerves, and their different components arise from centres of origin in the medulla oblongata and in the cervical region of the spinal cord which are directly continuous with the corresponding groups of nerve cells in other parts of the spinal cord. Here, however, the deviation from the spinal nerve type which has taken place consists not in the suppression of any particular component, but in the scattering of the various components, so that none of the nerves of this group form in themselves complete segmental nerves, but rather the whole of them taken together form a broken up group of segmental nerves which are capable of being rearranged not only into afferent and efferent but also into splanchnic and somatic divisions of precisely the same character as in a group of spinal nerves.

I conclude therefore that both these two great groups of cranial nerves are built up on the same plan as the spinal nerves, not only with respect to the structure, function, and distribution of their nerve fibres, but also as far as the arrangement of the centres of origin of those nerve fibres in the central nervous system is concerned; and I think it probable that the reason for the deviation of the cranial nerves from the spinal nerve type is bound up with the changes which occurred at the time when a large portion of the fibres of the foremost group of cranial nerves lost their functional activity. I imagine that in the long past history of the vertebrate animal some extensive tract in connection with the foremost part of the nervous system has become useless and disappeared, and in consequence the nerves supplying those parts have degenerated. In this phylogenetic degeneration the whole of the splanchnic and somatic afferent nerves of that region were involved, and probably also some of the efferent nerve fibres, with the result that certain only of the motor elements have remained functional. In the further history of the vertebrate, the parts which have replaced those which became useless have received their nerve supply from tracts of the central nervous system situated behind this foremost group of nerves; in consequence of which the component parts of that hindermost group have become more or less separated from each other. The extent of the area involved is especially well seen when the sensory nerves of this area, both somatic and splanchnic, are considered; for we see not only that the sensory part of the trigeminal, representing the somatic sensory elements, and the sensory part of the vagus, representing the splanchnic sensory elements, are derived from their respective ascending roots, *i.e.* arise in connection with a series of nerve segments extending well into the cervical region, but also that the peripheral distributions of these two nerves are very extensive. Without speculating further at present upon the nature of the change which has disturbed the orderly arrangement of the cranial nerves, enough has been said to prove that the cranial nerves considered in this article are built up on the same plan as the spinal nerves. Further it is worthy of notice that just as the division into somatic and splanchnic has thrown great light upon the conception of the manner in which a segmental nerve is formed, so also it lends aid to the consideration of the segmentation of structures other than the nervous, for we find that two distinct segmentations exist in the body which do not necessarily run parallel to each other: the one, a segmentation which may be fitly called splanchnic, and is represented by the orderly arrangement of visceral and branchial clefts; and the other, a somatic segmentation, characterized by the formation of somites, *i.e.* of vertebræ and somatic muscles arranged also in orderly sequence.

The splanchnic segmentation is most conspicuous in the cranial region, the somatic segmentation in the spinal region, and it is most advisable to remember that a valid comparison between cranial and spinal segments can only be made when like is compared with like, for it by no means follows that the somatic and splanchnic segmentations have proceeded on identical lines; consequently, in comparing cranial with spinal nerves, we must compare structures of the same kind, and seeing that the spinal nerves are arranged according to somatic segments so also must the cranial nerves be arranged in accordance with their relation to the somatic muscles of the head, and not in relation to the branchial and visceral clefts.

It is not advisable in this article to enter upon any discussion as to the number of segments supplied by the cranial nerves, or to speculate upon the nature of the changes which have taken place in the past history of the vertebrate animal, whereby the present distribution of the cranial nerves has been brought about. I desire only to put as shortly as possible before the readers of NATURE the general results of my recent investigations into the structure of the cranial and spinal nerves.

W. H. GASKELL.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. T. C. Fitzpatrick, of Christ's College, has been appointed an Assistant Demonstrator of Physics.

Prof. H. M. Ward, M.A., of Christ's College, has been appointed Examiner in Botany in the place of Prof. Bayley Balfour.

Dr. R. D. Roberts has been appointed an Elector to the Harkness Scholarship.

The name of Mr. Adami, the new Demonstrator of Pathology, was misprinted Adams in our last issue.

SCIENTIFIC SERIALS.

Bulletin de l'Académie Royale de Belgique, February.—Researches on the colloidal state, by C. Winssinger. This is the first part of a memoir describing a series of experiments undertaken to determine the various conditions of the colloidal state—that is, of the state assumed under certain circumstances by bodies generally insoluble in water. For the present the author confines himself to describing the mode of preparation and the chief properties of the colloidal substances. All the fifteen sulphides studied by him (those of mercury, zinc, tungsten, molybdene, indium, platinum, gold, palladium, silver, thallium, lead, bismuth, iron, nickel, and cobalt) have been obtained in the colloidal state. They bring up to thirty-one the number of colloids now known to science. Some have been prepared by Graham's method, others directly by treating the oxides suspended in the water with hydrosulphuric acid.—On the pretended pro-atlas of mammals and *Hatteria punctata*, by Jules Cornet. The bony process between the occipital and the atlas known as the pro-atlas or proto-vertebra, and found in crocodiles and some other reptiles, is here shown not to exist in the mammals as supposed by some naturalists. The view of Smets regarding its absence from Hatteria is also confirmed.—On the process employed by the fresh-water Gasteropods for crawling over the liquid surface, by Victor Willem. This process is shown to be somewhat analogous to that of snails moving on dry land, being effected by secreting a mucus which enables the mollusk to adhere to the surface.—Researches on the volatility of the carbon compounds; chloro-oxygenated compounds, by Louis Henry. The object of these researches is to examine, in reference to their volatility, the compounds in which chlorine and oxygen are simultaneously combined with carbon. The subject is discussed under three heads: (1) the compounds comprising the system $>C-O$; (2) the system $\rightarrow C-OX$; (3) the mixed derivatives simultaneously including both these systems.

Rendiconti del Reale Istituto Lombardo, March 22.—Observations made in the Brera Observatory, Milan, during the total lunar eclipse of January 28, 1888, by G. V. Schiaparelli. These observations were made under favourable conditions in accordance with the instructions issued by the Pulkova astronomers, with the ultimate view of determining more accurately than has yet been possible the exact length of the diameter of the moon. In the accompanying tables are given the results of the observations, comprising the comparison-stars with their magnitudes and numbers as in the catalogue distributed by the Pulkova astronomers.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 22.—"The Chemical Composition of Pearls." By George Harley, M.D., F.R.S., and Harald S. Harley.

(1) As regards oyster pearls. Of these, three varieties were examined—British, Australian, and Ceylonese.

The qualitative analyses showed that they all had an identical composition, and that they consisted solely of water, organic matter, and calcium carbonate. There was a total absence of magnesia and of all the other mineral ingredients of sea-water—from which the inorganic part of pearls must of course be obtained. Seeing that ordinary sea-water contains close upon ten and a half times more calcium sulphate than calcium carbonate, one might have expected that at least some sulphates would have been found along with the carbonates, more especially if they are the mere fortuitous concretions some persons imagine them to be; a view the authors cannot indorse, from the fact that by steeping pearls in a weak aqueous solution of nitric acid, they are able to completely remove from them all their mineral constituents without in any way altering their shape, and but very slightly changing their naked eye appearances, so long as they are permitted to remain in the solution. When taken out they rapidly dry and shrivel up. Dr. George Harley will take occasion to point out in his next communication, which will be on the microscopic structure of pearls, that a decalcified crystalline pearl bears an intimate resemblance to a decalcified bone, in so far as it possesses a perfectly organized matrix of animal matter. No phosphates whatever were found in any of the three before-named varieties of pearls.

The next point being to ascertain the exact proportions of the substances composing the pearls, and pure white pearls being expensive, from having ascertained that all the three kinds they were operating upon had exactly the same chemical composition, instead of making separate quantitative analyses of them, they simply selected two pearls from each variety, of as nearly the same size and weight—giving a total of 16 grains—and analyzed them collectively, the result obtained being: carbonate of lime 91·72 per cent; organic matter (animal), 5·94 per cent; water 2·23 per cent.

(2) Composition of cocoa-nut pearls.

A portion of a garden pea sized cocoa-nut pearl, weighing 14 grains, was subjected to analysis, and found that, like shell-fish pearls it consisted of carbonate of lime, organic matter (animal), and water.

It had all the external appearances of the pearls found in the large clams (*Tridacna gigas*) of the Southern Ocean, being perfectly globular, with a smooth, glistening, dull white surface, and resembling them exactly in microscopic structure. Besides which in chemical composition it bore no similarity to cocoa-nut milk, to which it is supposed to be related; for cocoa-nut milk is said to contain both the phosphate and the malate, but not the carbonate of lime. That there are pearls found in cocoa-nuts the authors do not presume to deny; all they mean to say is that they are doubtful if the specimen examined had such an origin.

(3) As regards mammalian pearls.

These so-called pearls have been met with in human beings and in oxen.

In so far as naked-eye appearances are concerned, a good specimen of the variety of pearl now spoken of is quite undistinguishable from a fine specimen of Oriental oyster pearl, from its not only being globular in shape, and of a pure white colour, but from its also possessing the iridescent sheen so characteristic of Oriental oyster pearls of fine quality.

In chemical composition, however, mammalian pearls bear no similarity whatever to pearls found in shell-fish, for they are composed of an organic instead of an inorganic material—namely, cholesterin. In microscopic structure again, they bear a marked resemblance to the crystalline variety of shell-fish pearls.

April 19.—"On Hamilton's Numbers. Part II." By J. J. Sylvester, D.C.L., F.R.S., Savilian Professor of Geometry in the University of Oxford, and James Hammond, M.A. Cantab.

§ 4. *Continuation, to an infinite Number of Terms, of the Asymptotic Development for Hypothenusal Numbers.*

In the third section of this paper (Phil. Trans. A., vol. clxxviii. p. 311) it was stated, on what is now seen to be insufficient evidence, that the asymptotic development of $p-q$, the half of any hypothenusal number, could be expressed as a series of powers of $q-r$, the half of its antecedent, in which the indices followed the sequence $2, \frac{3}{2}, 1, \frac{3}{4}, \frac{5}{8}, \frac{1}{2}, \ldots$

It was there shown that, when quantities of an order of magnitude inferior to that of $(q-r)^{\frac{3}{4}}$ are neglected,

$$p-q=(q-r)^2+\tfrac{4}{3}(q-r)^{\frac{3}{2}}+\tfrac{11}{18}(q-r)+\tfrac{10}{81}(q-r)^{\frac{3}{4}};$$

but, on attempting to carry this development further, it was found that, though the next term came out $\frac{88}{1215}(q-r)^{\frac{5}{8}}$, there was an infinite series of terms interposed between this one and $(q-r)^{\frac{1}{2}}$.

In the present section it will be proved that between $(q-r)^{\frac{3}{4}}$ and $(q-r)^{\frac{1}{2}}$ there lies an infinite series of terms whose indices are—

$$\tfrac{5}{8}, \tfrac{9}{16}, \tfrac{17}{32}, \tfrac{33}{64}, \tfrac{65}{128}, \ldots$$

and whose coefficients form a geometrical series of which the first term is $\frac{88}{1215}$ and the common ratio $\frac{2}{3}$.

We shall assume the law of the indices (which, it may be remarked, is identical with that given in the introduction to this paper as originally printed in the *Proceedings* but subsequently altered in the Transactions), and write—

$$\begin{aligned} p-q &= (q-r)^2+\tfrac{4}{3}(q-r)^{\frac{3}{2}}+\tfrac{11}{18}(q-r)+\tfrac{10}{81}(q-r)^{\frac{3}{4}} \\ &+\frac{2^3}{3^3}A(q-r)^{\frac{5}{8}}+\frac{2^4}{3^4}B(q-r)^{\frac{9}{16}}+\frac{2^5}{3^5}C(q-r)^{\frac{17}{32}} \\ &+\frac{2^6}{3^6}D(q-r)^{\frac{33}{64}}+\frac{2^7}{3^7}E(q-r)^{\frac{65}{128}}+\text{\&c., } ad\ inf. \quad \ldots (1) \\ &+\Theta\,^* \end{aligned}$$

The law of the coefficients will then be established by proving that—

$$A=B=C=D=E=\ldots\ldots=\tfrac{11}{45}.$$

If there were any terms of an order superior to that of $(q-r)^{\frac{1}{2}}$, whose indices did not obey the assumed law, any such term would make its presence felt in the course of the work; for, in the process we shall employ, the coefficient of each term has to be determined before that of any subsequent term can be found. It was in this way that the existence of terms between

* In the text above, Θ represents some unknown function, the asymptotic value of whose ratio to $(q-r)^{\frac{1}{2}}$ is not infinite.

$(q - r)^{\frac{5}{8}}$ and $(q - r)^{\frac{1}{2}}$ was made manifest in the unsuccessful attempt to calculate the coefficient of $(q - r)^{\frac{1}{2}}$.

It thus appears that the assumed law of the indices is the true one.

It will be remembered that $p, q, r,$ . . . . are the halves of the sharpened Hamiltonian Numbers $E_n + 1$, E_n, $E_n - 1$, ... and that consequently the relation—

$$E_{n+1} = 1 + \frac{E_n(E_n - 1)}{1 \,.\, 2} - \frac{E_{n+1}(E_{n-1} - 1)(E_{n-1} - 2)}{1 \,..\, 2 \,...\, 3} + \;.\;.\;.\;.$$

may be written in the form—

$$p = \tfrac{1}{2} + \frac{q(2q-1)}{2} - \frac{r(2r-1)(2r-2)}{2 \,.\, 3} + \frac{s(2s-1)(2s-2)(2s-3)}{2 \,.\, 3 \,..\, 4}$$
$$- \frac{t(2t-1)(2t-2)(2t-3)(2t-4)}{2 \,.\, 3 \,...\, 4 \,..\, 5}$$
$$+ \frac{u(2u-1)(2u-2)(2u-3)(2u-4)(2u-5)}{2 \,...\, 3 \,.\, 4 \,.\, 5 \,...\, 6}$$
$$- \;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;. \qquad (2)$$

The comparison of this value of p with that given by (1) furnishes an equation which, after several reductions have been made in which special attention must be paid to the order of the quantities under consideration, ultimately leads to the determination of the values of A, B, C, ... in succession.

Physical Society, April 14.—Shelford Bidwell, F.R.S., Vice-President, in the chair.—Mr. W. E. Sumpner read a paper on the variation of the coefficients of induction. The author pointed out that there are three ways of defining the coefficient of self-induction of a circuit, expressed by the following equations—

$$(1)\quad e = L_1 \frac{dC}{dt}\;; \qquad (2)\quad N = L_2 C\;;$$
$$(3)\quad T = \tfrac{1}{2} L_3 C^2\;;$$

where e = back E.M.F. due to change of current, C = current, N = total induction through the circuit, and T the kinetic energy of the circuit. If the medium be air, L_1, L_2, and L_3 are identical, but in the case of iron this is no longer the case. When the curve of magnetization is given, their values, corresponding with any value of C, can be easily determined by the above equations. Maxwell's absolute method of measuring self-induction gives L_2, and by a modification due to Prof. Ayrton, where the current is altered from C_1 to C_2 instead of from 0 to $C = \frac{C_1 + C_2}{2}$, the value of L obtained is approximately L_1, if $C_1 - C_2$ is small compared with C. From the known character of the curves of magnetization of iron, it is easily seen that the value of L_2 increases with the current when the current is small, then becomes nearly constant, and afterwards decreases. For an electro-magnet having a horse-shoe core of best Swedish iron ½" diameter and 14" long, wound with 800 convolutions, the value of L_2 for currents between ·047 and ·107 amp. was found to satisfy the equation $L_2 = \frac{A}{5} + {\cdot}0425$, where A = current in amperes. A method of comparing self-induction with capacity is described, in which the arm of a Wheatstone's bridge opposite the one containing self-induction is shunted by a condenser of capacity K. The bridge is balanced for steady currents, and the deflection, θ_1, of the galvanometer observed on breaking the battery circuit. θ_1 is : : $L_2 - Kps$, where p and s are the resistances of the two remaining arms of the bridge. The condenser is then disconnected, and another swing, θ_2, obtained, on again breaking the battery circuit. θ_2 is : : L_2,

$$\therefore\; \frac{\theta_2}{\theta_1} = \frac{L_2}{L_2 - Kps}\;, \text{ or } L_2 = \frac{\theta_2}{\theta_2 - \theta_1} Kps.$$

Further experiments were made on the electro-magnet when its poles were joined by a piece of soft iron, the currents being reversed. The resulting values of L_2, $\mathfrak{B}$, $\mathfrak{H}$, and μ are given in absolute measure, and from them the author deduces—

$$L_2 = {\cdot}05 + 3{\cdot}9\,A, \qquad \mu = 210 + 720\,\mathfrak{H},$$
$$\mathfrak{B} = 210\,\mathfrak{H} + 720\,\mathfrak{H}^2, \quad \text{for values of A between ·06 and ·9.}$$

The difficulties experienced in determining the induction coefficients for strong magnetizing forces produced by the testing current are described. They arise chiefly from the fact that in order to obtain strong currents, the resistances must be small. This makes the "*time constant*" large, and in order to obtain the values of L in absolute measure, a ballistic galvanometer of very long period would be required. A method of calibrating a galvanometer of comparatively short period to give approximate results is described. Where the magnetizing force is produced by an independent coil, no such difficulties present themselves. Results obtained for the coefficients of self-induction of a gramme armature (A type) for different currents round the field magnets vary from ·0218 for current 0 to ·0117 for a current of 29 amperes. The value of L for a given point on the curve of magnetization is not a definite quantity, but has always two or more distinct values, depending on whether the magnetization is increased or decreased by the test currents, and on the previous history of the iron. That this must be the case is easily seen from the curves obtained by Prof. Ewing in his "Experimental Researches on Magnetism." The values of L corresponding to the three sides of a small Ewing's cycle are denoted by L_p (*progressive coefficient*), L_r (*return coefficient*) and L_c (*cyclic coefficient*). L_p is always the largest, whether the magnetization be increased or decreased by the testing current. Numerical values of L_p and L_c obtained from a Kapp and Snell transformer are given. L_c can be very accurately determined by Profs. Ayrton and Perry's secohmmeter, and some of the results given in the paper were thus obtained. Having given the curve of magnetization and that connecting impressed E.M.F. and time, a simple graphical method is described for drawing the current curve. Applying this to an alternating current where the E.M.F. is a pure sine function of the time, it is shown that the resulting current curve differs considerably from a sine curve. The case of the rise of current in the magnet coils of a dynamo excited by accumulators is also discussed, the derived curves being in accordance with observation. In conclusion the author pointed out that the time taken to discharge a condenser through a given resistance may be decreased by adding self-induction to the circuit, provided L is less than $\frac{1}{2}KR^2$. When $L = \frac{1}{4}KR^2$, the discharge is completed in one-half the time required when L = 0. This may account for the remarkable results observed by Dr. Lodge in his experiments on iron and copper as lightning-conductors.—Mr. C. V. Boys described and performed some experiments on soap-bubbles, and by their aid demonstrated in a remarkable manner the phenomena of surface tension, diffusion, and the magnetic properties of gases. By blowing one bubble inside another, he showed that there is no electrical force inside a closed conductor. A peculiar property of soap-bubbles is their refusal to come into contact when knocked against each other; they may receive violent shocks and still remain separate. If, however, an electrified body be brought in the vicinity, they immediately coalesce. So sensitive are they to electrical attraction that a potential difference due to one Leclanché cell between the two bubbles causes them to unite. They may thus serve as very delicate electroscopes. Many other beautiful and extremely interesting experiments on liquid films of different shapes were performed in a masterly manner.

Geological Society, April 11.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—On the lower beds of the Upper Cretaceous series in Lincolnshire and Yorkshire, by W. Hill.—On the Cae Gwyn Cave, North Wales, by Dr. Henry Hicks, F.R.S.; with an appendix by C. E. De Rance. The author gave an account of the exploration of the cavern during the latter part of 1885, and during 1886–87. He considered that the results obtained during that time proved conclusively that there was no foundation for the views of those who contended that the drift which covered over the entrance and extended into the cavern was *remanié*, but they proved that the deposits which lay over the bone-earth were *in situ*, and were identical with the normal glacial deposits of the area. These deposits had once extended continuously across the valley, and the cavern (400 feet above Ordnance datum) had consequently been completely buried beneath them. The cave must have been occupied by animals during the formation of the bone-earth, before any of the glacial deposits now found there had accumulated, and a thick floor of stalagmite had covered this "earth" before the cavern had been subjected to water-action. This action had broken up the floor, and completely re-sorted the materials, and added sandy and gravelly material to the deposits; this sand and gravel had been examined by Prof. Boyd Dawkins, who found that it agreed in every particular with the glacial sand

and gravel occurring in the valley a little way above. The large limestone blocks in the cavern had also been evidently disturbed by water-action; they were invariably found in the lowest deposits, and were covered over by laminated clay, sand, and gravels. The author considered it certain that the caverns had been completely filled with these materials, and in the case of the Cae Gwyn Cave they appeared to have been conveyed mainly through the entrance recently discovered under the drift. The stratification at this entrance was so marked, and could be traced so continuously inwards over the bone-earth, that there could be no doubt that this was the main entrance. There was not the slightest evidence that any portion of the material had been conveyed in through a swallow-hole, and the conditions witnessed throughout were such as to preclude any such idea. The author quoted a Report by Dr. Geikie, who considered that the wall of the cavern had given way, but before the deposition of the glacial deposits, which were subsequently laid down against the limestone bank so as to conceal this entrance to the cavern. In conclusion, he referred to the presence of reindeer remains in these caves, in conjunction with those of the so called older Pleistocene Mammalia, proving that these had reached the area long before the period of submergence, and evidently at an early stage in the Glacial period. It was important to remember that reindeer remains had been found in the oldest river-gravels in which implements had been discovered. Man, as proved by the implements discovered, was also present at the same time with the reindeer, and it was therefore natural to suppose that he migrated into this area in company with that animal from some northern source, though this did not preclude the idea that he might also have reached this country from some eastern or southern source, perhaps even at an earlier period. In the course of the discussion which followed the reading of this paper, Dr. Evans said the archæological evidence was against Dr. Hicks's views.

Chemical Society, April 19.—Mr. W. Crookes, F R.S., in the chair.—The following papers were read:—The influence of temperature on the composition and solubility of hydrated calcium sulphate and of calcium hydroxide, by Messrs. W. A. Shenstone and J. T. Cundall. The authors find, contrary to the usual statements on the subject, that hydrated calcium sulphate, whether of natural or of artificial origin, parts with a portion of its water at moderate temperatures, *e.g.* 40° C., and that it may be almost completely dehydrated in dry air at temperatures below 100° C. The effect of heat in diminishing the solubility of calcium sulphate in water at temperatures between 40° and 150° may therefore be possibly due to the unequal solubility of the hydrated and anhydrous salts. Calcium hydroxide is likewise less soluble in hot than in cold water, but the authors have failed to obtain evidence in favour of the view that the diminished solubility in this case may depend upon the dissociation of the hydroxide or of some hydrate of the hydroxide.—Thermo-chemical constants, by Mr. S. U. Pickering. In a criticism of several deductions drawn by Thomsen from thermo-chemical data, the author refers to the supposed "common constant of affinity"—a quantity whose multiples by numbers up to 10 are supposed to represent various reactions, some of which are similar, and others totally dissimilar (*Ber. Deutsch. Chem. Ges.*, v. 170, vi. 239); and points out that any number taken at random, *e.g.* 15,000 cal., would have given results similar to those obtained by employing Thomsen's value of the constant, viz. 18,361 cal.—Action of hot copper on the mixed vapours of phenol and carbon bisulphide, by Prof. T. Carnelly and Mr. J. Dunn. A small yield of a new diphenylene ketone (m.p. = 83°) is obtained in this reaction.—Oxidation of oxalic acid by potassium bichromate, by Mr. E. A. Werner.—The action of phenylhydrazine on urea and on some of its derivatives, by Mr. S. Skinner and Dr. S. Ruhemann.—Derivatives of phenylisobutyric acid, by Dr. L. Edeleanu.—The logarithmic law of atomic weights, by Mr. G. J. Stoney, F.R.S.

Zoological Society, April 17.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of March 1888.—Mr. C. Stewart exhibited a preparation showing the structure and development of the brood-pouch of a Marsupial Tree-Frog (*Nototrema marsupiatum*).—Mr. Boulenger exhibited and made remarks on the type specimen of a new species of Marsupial Tree-Frog (*Nototrema fissipes*) recently discovered by Mr. G. A. Ramage near Pernambuco, in Brazil.—Mr. Herbert Druce read the descriptions of some new species of Heterocera collected by Mr. C. M. Woodford at Suva, Viti Levu, Fiji Islands. The collection had been made during the months of February, March, and April, 1886, and was especially interesting on account of the exact localities being noted, as well as for the new species it contained. Ninety-four species were represented, eight of which were described by the author as new to science.—A communication was read from Mr. T. D. A. Cockerell, containing some remarks on atavism, with reference to a paper on the same subject read by Mr. J. Bland Sutton at a previous meeting of the Society.—Prof. G. B. Howes gave an account of the vocal pouch of *Rhinoderma darwini*, and described in detail the mode of its attachment and the position of the embryos in it. The author controverted the idea of Espada that the alimentary functions were arrested during the development of the embryos in this Batrachian.—Mr. Oldfield Thomas read a paper describing a new genus and species of Muridæ obtained by Mr. H. O. Forbes during his recent expedition to New Guinea. The author proposed to call this form, which was characterized by the possession of a prehensile tail, *Chiruromys forbesi*, after its discoverer.—Lieut.-Colonel Godwin-Austen, F.R.S., read the first of a proposed series of papers on the Land-Mollusca of Burma. The present communication gave an account of the shells collected by Capt. Spratt, R.A., in Upper Burma, among which were specimens of several new and very interesting species. A communication was read from Mr. R. Bowdler Sharpe, containing the sixth of his series of notes on the specimens of the Hume collection of birds. The present paper treated of some of the species of the genus *Digenea*.

Anthropological Institute, April 24.—Francis Galton, F.R.S., President, in the chair.—A paper by Dr. Venn on recent anthropometry at Cambridge was read, and was followed by a communication by the President on the head-growth of Cambridge students. The President's paper we print elsewhere. Mr. Galton also read a paper on the answers he had received from teachers in reply to questions respecting mental fatigue.

Paris.

Academy of Sciences, April 23.—M. Janssen, President, in the chair.—Influence of gravity on the co-ordinates measured by means of equatorials, by MM. Lœwy and P. Puiseux. The paper deals mainly with the equatorials *coudés*, such as the large instrument intended for the Paris Observatory, and gives the general formulas of reduction.—On the aperiodic regulation of the amortisement and of the phase in a system of synchronized oscillations, by M. A. Cornu. The principle is explained of this aperiodic method of control, which is shown to possess several advantages over the systems at present in use. It reduces to a minimum, if not to zero, the influence of the more ordinary disturbing causes, and supplies a continuous check for the regulating apparatus as well as a simple means of readjustment should it get out of order.—Remarks on M. Stoletow's recent communication on a class of electric currents set up by the ultraviolet rays, by M. Edm. Becquerel. The note referred to the passage of an electric current between two disks, or metallic conductors, placed parallel to, and at a little distance from, each other, by means of the layer of intervening air, which requires to be more or less heated by the radiation of a voltaic arc. M. Becquerel points out that these effects appear to be analogous to those which he observed and analyzed in a different way in the year 1853. He then showed that heated gases may conduct electric currents, these effects being functions of the nature and density of the gases, as well as of the relative dimensions of the electrodes.—On the fixation of nitrogen by vegetable soil, by M. Berthelot. This is a reply to M. Schlœsing's recent remarks, the main object of the note being to more clearly establish the history of these researches and their present character.—On the optical properties of natural pharmacolite, by M. Des Cloizeaux. The author, having recently resumed his interrupted studies of this crystal, finds that its optical crystallographic properties are absolutely identical with those of the artificial crystals lately obtained by M. Dufet. The only difference is an excess of about 4 per cent. of water as determined by previous analyses of the natural crystals. But these crystals are hygrometric, and lose some of their water at 100° C. The specimens analyzed were also probably mixed with a little wapplerite, which has yielded as much as 29 per cent. of water, and which in the state of an efflorescent powder is usually associated with pharmacolite.—Note on the optical characters of haidingerite, by M. Des Cloizeaux. An examination of some small specimens of this extremely rare crystal found in association with a few fragments of pharmacolite shows that it must be grouped with the family of the positive acute bisector crystals. One of its indices of refraction, formerly measured by Haidinger on a natural prism of 40°, formed by two opposite facets, *h'* and *m*, must be the maximum index, $\alpha = 1·67$.—Observations of Palisa's new planets 275 and 276, made at the Observatory of Algiers, by MM. Trépied, Rambaud, and Sy. These observations, which were made with the 0·50 m. telescope, cover the period April 17-18, when the two planets were of the respective estimated magnitudes 11 and 11·5.—On the employment of gas thermometers, by M. Crafts. These remarks are made in connection with the hydrogen instrument recently described by M. Cailletet, who mentions an analogous type of thermometer devised ten years ago by M. Crafts.—On a new system of telephonic communication between trains in motion and the neighbouring stations, by M. P. Germain. A series of electric measurements effected on rails from the stand-point of their resistance, insulation, and diffusive electric power, has satisfied the author that the two metallic parts of the same line connected together constitute an excellent conductor, provided the circuit and pile be insulated from earth. He has established curves of resistance for the rails according to the variations caused by the temperature and by the humid condition of the ballast. A new line shows less resistance than an old, owing to the oxidation of the points and the slow transformation brought about in the molecules of steel under the influence of vibration. By setting up the necessary apparatus in the stations and in the guard's van, telephonic correspondence may be carried on in both directions; but the details of the process are for the present withheld.—On a new fossil fish of the Commentry (Allier) Coal-measures, by M. Charles Brongniart. This fish, of which several good specimens have been found, presents peculiarities distinguishing it from all other fishes extinct or living. It is here consequently constituted a separate order of Pleuracanthides, as the prototype of the star-fish, Ceratodus, and allied forms. The present specimen is named *P. gaudryi*, in honour of M. Albert Gaudry.

BERLIN.

Physiological Society, April 13.—Prof. Munk, President, in the chair.—Prof. Gad made a complementary communication to his previous one dealing with the proof of the Wallerian law. His experiments were carried out, in conjunction with Dr. Joseph, on the vagus nerve and its jugular ganglion. The nerve was cut through either on the central or peripheral side of the ganglion, and after six or eight weeks degeneration was looked for in the ganglion and nerve. These experiments yielded only a general confirmation of Waller's law; at the same time they brought to light so many peculiarities and divergencies, that, even with the help of physiological experiment, it was found impossible to deduce any universal laws from the details communicated to the Society.—Dr. Baginski spoke on the Bacteria normally present in the fæces of children which are being fed on the milk of the mother. As is well known, Eschricht has distinguished two kinds among the above, viz. *Bacterium lactis* and *Bacterium coli*; of these the first is said to be capable of inducing the lactic fermentation of milk-sugar. The speaker had investigated the truth of this statement by cultivating the *Bacterium lactis*, with all needful precautions, in a solution of milk-sugar to which neither peptone nor any other nutrient fluid had been added. When the fermentation was at an end, the fluid was strongly acid, but no lactic acid, or at most the minutest trace of this acid, could be discovered in it: all the reactions which it did yield pointed to the presence in it of acetic acid. This *Bacterium lactis* (which should now rather perhaps be called *Bacterium aceti*) produced no effect on casein or any other proteid, and no putrefactive change was induced. Similarly it had no action on starch paste. Bearing in mind the practical medical interest which attaches to fermentative processes which may occur in the alimentary canal of children at the breast, Dr. Baginski had next investigated the behaviour of the Bacterium and the nature of the fermentation it produces when deprived of air and oxygen, and found that the fermentation was in all respects the same as that which takes place with access of air. The gaseous products of the fermentation were carbonic acid gas, hydrogen and marsh-gas. From among the various substances whose action on the Bacterium was tried, it is sufficient to mention that acetic acid very speedily killed it, so that no growth of the organism was observed in gelatine made acid with the product of its own activity. This product therefore plays the part of an active poison as regards the further life of the organism.—Dr. Mertsching spoke on the histology of the skin and hairs, and in some detail on the mode of origin of horny growths. The speaker exhibited a large number of preparations in support of his views.

AMSTERDAM.

Royal Academy of Sciences, March 31.—Mr. Martin stated that he had been charged by Mr. van Lansberge, late Governor-General of Dutch India, to present to the Leyden Museum a portion of a jaw of a gigantic Ichthyosaurus from the south coast of Ceram. From this fossil the existence of Mesozoic strata in that island may be inferred; and the fact that in British India and in Australia remains of the same animal have been found in the Chalk suggests that in Ceram also there may be a Cretaceous formation. The statement made in Berghaus's Physikalischer Atlas, to the effect that a Palæozoic formation is to be found on the south coast of Ceram, is without foundation.

BOOKS, PAMPHLETS, and SERIALS RECEIVED FOR REVIEW.

FORMS OF ANIMAL LIFE.

Forms of Animal Life. A Manual of Comparative Anatomy, with Descriptions of Selected Types. By the late George Rolleston, D.M., F.R.S., Linacre Professor of Anatomy and Physiology in the University of Oxford. Second Edition, Revised and Enlarged by W. Hatchett Jackson, M.A., Natural Science Lecturer, St. John's College, Oxford. (Oxford: Clarendon Press, 1888.)

THE first edition of Prof. Rolleston's "Forms of Animal Life" was published in 1870. Avowedly an educational work, and written expressly for students, it came at a time when the teaching of zoology was in a very different position from that which it now holds, and opportunities for systematic laboratory instruction were rare.

At Oxford there already existed an admirably equipped Museum, in the arrangement of which the wants of students received special attention; facilities for laboratory work were also offered, and among the Linacre Professor's pupils were men destined to become the leaders of the younger school of English zoologists. Elsewhere, however, the conditions were less favourable. The Cambridge school of biology, which has made for itself so great and honourable a reputation, as yet had no existence. Indeed, it was not till the year of publication of Prof. Rolleston's volume that the Trinity Prælector in Physiology entered on the duties of his new office; and it was in October of the same year that the late Prof. Balfour commenced his brilliant University career.

In other centres the state of things was very similar. Zoology was taught almost exclusively by lectures, often indeed of great value, but supplemented at most by demonstrations. Individual students worked hard at dissections or in museums, but organized laboratory instruction, in direct connection with systematic lectures, existed on a very small scale, if at all.

There was, however, a firm conviction on the part of those most directly and intimately concerned, that a great change was necessary; and a determination to carry out this reform at the earliest possible opportunity. In 1872, Prof. Huxley entered into possession of the new Biological Laboratories at South Kensington, and at once inaugurated a system of combined lecture and laboratory instruction which has formed the model on which all subsequent courses have been framed. Three years later he published, in conjunction with Prof. Martin, the "Course of Elementary Instruction in Practical Biology," and from that time the teaching of biology by lectures only became impossible.

This same year, 1875, witnessed the commencement of Prof. Balfour's systematic courses of practical morphology at Cambridge, and the introduction, by its newly elected Professor of Zoology, of the reformed system into one of the most eminent of the London medical schools. The change spread rapidly throughout the country, and the adoption of the new methods of teaching, pushed to its logical conclusion, led to the establishment of numerous appointments, and to the building and equipment of the splendid Laboratories at Cambridge, Manchester, and elsewhere.

It would not be wise to attempt to estimate too accurately to what extent Prof. Rolleston's book was instrumental in bringing about this reform, by which the whole scope and method of biological teaching were altered. It must be noted, however, that the time of its appearance was most opportune, and that the two leading principles of the book, in which it differed most markedly and most deliberately from all other works of the time, were precisely the characteristic features of the new school. These are, in the first place, the insistence on accurate and practical examination of selected types before a student is allowed to proceed to the systematic study of the groups to which the types belong; and, secondly, the importance of direct reference to the original sources of information. On the first of these points, Prof. Rolleston says, in his preface:—

"The distinctive character of the book consists in its attempting so to combine the concrete facts of zootomy with the outlines of systematic classification as to enable the student to put them for himself into their natural relations of foundation and superstructure. The foundation may be made wider, and the superstructure may have its outlines not only filled up, but even considerably altered, by subsequent and more extensive labours; but the mutual relations of the one as foundation and of the other as superstructure, which this book particularly aims at illustrating, must always remain the same."

On the importance of direct reference to the original authorities he speaks very positively:—

"In some cases, even the beginner will find it necessary to consult some of the many works referred to in the descriptions of the preparations and in the descriptions of the plates; but the bibliographical references have been added with a view rather to the wants indicated in the words 'Für akademische Vorlesungen und zum Selbststudium,' so often prefixed to German works on science, than to those of the commencing student."

"Forms of Animal Life" was the first student's text-book in which these principles were distinctly formulated and deliberately adopted; and there can be no doubt that it played a most important part in stimulating and enforcing a direct study and accurate acquaintance with type forms as a necessary prelude to systematic zoological work: just as the admirable series of preparations by Mr. Robertson, the description of which forms so characteristic and important a feature of the book, have furnished a model from which other museums have copied freely and to their great advantage.

Prof. Rolleston took great interest in his book: during the later years of his life he was actively engaged in preparing the second edition; and very early in this work he asked Mr. Jackson to act with him as joint author. Some progress was made in this joint work, but it was soon interrupted by the illness which, in the winter of 1880, compelled Prof. Rolleston to go abroad, and which proved fatal only a few months later.

"When Prof. Rolleston went abroad," says Mr. Jackson, "he put me in possession of his plans for the rest of the work, handed his papers to me, and expressed a hope that, if he were disabled from completing the new edition, I might be the person to do it in his stead. It is almost needless for me to add that in fulfilling this sacred trust

I have endeavoured to carry out his wishes, which were mainly three: (1) to enlarge the descriptions of the preparations and accounts of the various classes of animals, and to bring them to the standard of contemporary knowledge; (2) to add to each class or group a brief classification; and (3) to give as full a bibliography as space would admit."

The new edition which is now before us has been most carefully revised throughout; very considerable additions have been made, especially in the systematic portion, which has been entirely re-written by Mr. Jackson; and the volume is more than double the size of its predecessor—extending to upwards of 900 pages.

The book, as before, consists of three main sections: the descriptions of the selected preparations; the descriptions of plates illustrating the salient features in the anatomy of certain of these types; and, thirdly, the systematic accounts of the several groups into which the animal kingdom is divided. The arrangement of these sections has been altered; for while in the former edition the descriptions of the preparations and plates were placed after the systematic part, the relative positions have in the new edition been reversed. The present arrangement is a more natural one, and the change, which was contemplated by Prof. Rolleston, is certainly an improvement.

The selected preparations, the description of which forms the first section of the book, are for the most part the same as those of the former edition. The skeleton and certain parts of the muscular system of the rabbit, and the alimentary canal, urinary, and generative organs of the same animal, have been added; the privet hawk moth has been substituted for the death's head; and the skeleton of the pigeon and a few invertebrate preparations have been omitted. Though the number of the preparations remains practically the same as before, this portion of the book has been increased by nearly a hundred pages; the expansion being due mainly to the insertion of much fuller accounts of allied forms, and partly to a large addition in the bibliography.

It would be an easy matter to take exception to the plan of this part of the book, and to urge that the space devoted to the description of particular specimens, which the majority of readers can never have a chance of seeing, might have been allotted, with far greater advantage to students, to thorough descriptions of the anatomy of typical animals selected as representatives of the several groups. Accounts such as these are much wanted, and the opportunity for providing them was an exceptionally favourable one. The criticism, however, loses all point as directed against this second edition, for Mr. Jackson, regarding his task as a trust, has rightly refrained from interfering with the scheme of arrangement of this, perhaps the most characteristic section of the book.

He has, however, subjected the whole to very careful revision. The descriptions are admirably clear and concise, and the additional paragraphs have given Mr. Jackson opportunity for introducing references to allied forms which are always important, and in many cases of very high value indeed.

The second part of the book, containing the plates with their descriptions, is less satisfactory. Of the twelve plates of the first edition ten have been retained without change, one has been slightly altered, and one cancelled. Three new plates, which had been prepared and completed under Prof. Rolleston's own direction, have been added, illustrating points in the anatomy of the skate, of the oyster, and of certain Arthropoda respectively. We sincerely wish these plates had been omitted. They form no essential part of the book; the subjects are not well chosen; and the drawings themselves are not always correct. The figure of the reproductive organs of the earthworm, for instance, is very misleading; and the nephridia, as shown in the same figure, are entirely wrong. The new plates show no improvement on the old ones: the figure of the oyster is not of sufficient importance to justify its insertion, while the plate supposed to illustrate the anatomy of the skate is one of the very worst we have ever seen. We cannot but feel the highest respect for the conscientious and self-effacing spirit in which Mr. Jackson has carried out a most laborious and delicate task; but we believe most sincerely that he would have done more honour to the memory of his chief by suppressing most if not all of these plates, which are in every way unworthy of the book and of its authors. From the fact that this part of the book has alone undergone compression, we suspect that Mr. Jackson, who has no responsibility in connection with the plates save that of retaining them, agrees with us as to their merits.

About a dozen woodcuts have been inserted in the descriptions of the preparations: these are well chosen and will prove useful, though the absence of descriptions in two or three cases is somewhat exasperating. At the present time accurate and original figures illustrating the anatomy of typical animals are so urgently needed that we cannot but regret that the resources of the Clarendon Press were not drawn on more largely in this respect.

The third and concluding portion of the book contains the systematic descriptions of the groups; and here the changes are very great indeed. Occupying less than two hundred pages in the former edition, it has now increased to six hundred. This part of the book is by far the most important, and is exceedingly well done. Short descriptions of the larger groups are followed by most accurate and comprehensive accounts of the several classes. The further subdivision of the classes into orders and other minor groups is given in all cases; and the most recent researches are referred to, without being given undue prominence.

For this part of the work Mr. Jackson is entirely responsible, and we congratulate him very heartily on the admirable manner in which he has effected it. We have indeed but one complaint to make—namely, that, as in the former edition, the groups are described in descending order, Vertebrates being taken first, and Protozoa last. This is a serious fault, giving the effect of an uncomfortable drop as we pass from group to group, and, furthermore, rendering discussion of the mutual relations of the several groups very difficult, and in many cases futile or impossible.

Apart from this, we have nothing but praise to offer. Limits of space will not allow that we should deal at length with the several classes, but a few points may be noted.

The Enteropneusta are left among the "Worms"; their vertebrate affinities are mentioned, though Mr.

Jackson does not appear to favour their claims to rank among the higher group. The vexed question of the homologies of the Arthropod appendages is treated fully The antennules of Crustacea are doubtfully classed as true appendages, while the Crustacean antennæ, with the cheliceræ of Arachnida are regarded as post-oral appendages which have become pre-oral by shifting forwards. The antennæ of Myriapods and Insects are ruled out, "as being apparently processes of the procephalic lobes;" while the suggestion that the telson represents a region rather than a somite will meet with very general approval.

Brauer's classification of Insects is adopted, with some slight modifications, and is given in considerable detail. The leeches are treated with caution as an isolated group, and no suggestion is made of their possible affinities with Turbellaria.

Among the lower groups the Cœlenterata are dealt with very thoroughly. The possibility of near kinship between the Acraspedote Medusæ and the Anthozoa that has found favour of late with Götte and others is mentioned, but rejected. The Protozoa also receive very liberal and thorough treatment, more than a hundred pages being devoted to them. As regards classification three main divisions are adopted: the Acinetaria, Ciliata and Mastigophora are classed together as Plegepoda, a group equivalent to the Stomatophorous Corticata of Lankester, and for which the old term Infusoria might conveniently be used. The remaining divisions are the Endoparasita or Sporozoa, and the Rhizopoda, the latter group being equivalent to Lankester's Gymnomyxa.

Mr. Jackson is a singularly modest writer, and seldom allows his own hand to be seen; a note on the blood-vessels of the earthworm, in which he questions the existence of the so-called subintestinal vessel, is of considerable interest; and throughout the volume there is abundant evidence of intimate practical acquaintance with the groups he describes so well.

The importance, even for the junior student, of direct reference to original papers was, as we have noticed above, one of the points on which Prof. Rolleston insisted most strongly. In this respect Mr. Jackson has afforded assistance of a singularly efficient character. Possessed of a most unusually accurate and extensive acquaintance with the zoological literature of all countries, Mr. Jackson has given the full benefit of his knowledge to readers of his book. Every page teems with evidence of the most diligent research amongst authorities, and none but a specialist in each group can estimate rightly the enormous amount of labour that its preparation must have cost him. Only less admirable is the restraint which has enabled him to refrain from burdening the book with an undue number of references, while those that are given have been selected with the utmost care, and arranged in such way as to afford the student aid of a kind hitherto denied him. "The method I have adopted," says Mr. Jackson, "is to cite the most important and recent authorities, which, when consulted, will in most cases give the names of all other accounts worth reading, so as to form a really very complete index to the state of present knowledge." It is this "index" which constitutes the characteristic feature of the new edition; and in the care and thoroughness with which he has compiled it, Mr. Jackson has conferred an inestimable boon on zoologists, and has rendered his work indispensable to teachers and students alike.

The earlier edition of "Forms of Animal Life" was marked by a certain singularity, at times almost grotesqueness, of diction, which interfered to some extent with the popularity of the book; we are glad to observe that care has been taken to remove this blemish, though an occasional tendency to reversion may be noticed in such statements as that "the anterior prostate is divaricable into two lobes," or that a given figure is "one-half less than natural size."

It would be better, too, if zoologists could completely emancipate themselves from the traditions of human anatomy, and cease to speak of the anterior part of a rabbit as the "upper half," or to use such terms as "vena cava descendens." "Uro-genital," too, which threatens to establish itself permanently, should not be used for urino-genital; and the term "pseud-hæmal" is objectionable, and, as applied to the vascular system of an earthworm, meaningless.

However, these are but small points; and in concluding we acknowledge in the fullest degree the singularly painstaking and conscientious manner in which Mr. Jackson has fulfilled his task, and the signal service he has thereby rendered to zoologists. "Forms of Animal Life" is a unique book; none but Prof. Rolleston could have written it; and probably there is no one who could have retained and developed more successfully than Mr. Jackson has done the exactness and thoroughness to which Prof. Huxley long ago alluded as its special charm.

A M. M.

THE CARDINAL NUMBERS.

The Cardinal Numbers, with an Introductory Chapter on Numbers Generally. By Manley Hopkins. London: Sampson Low, 1887.)

UNLIKE Hudibras, who could, as we are told, "extract numbers out of matter," Mr. Hopkins proposes in the essay before us to extract matter from numbers, or, as he says in the preface, "to show that every-day things—numbers being one of them—possess in themselves materials worth investigation, and connections with other subjects of thought and study." Our author does not attempt any systematic investigation of the properties of numbers: to do so would far transcend the modest limits to which he confines himself. He prefers to consider numbers in their relation to such subjects as religion, music, poetry, mythology, and superstition. Some purely numerical facts are, however, given, which either are, or else ought to be, found in every text-book of arithmetic—for instance, the rules (given on p. 75, at the beginning of the appendix) for determining when a number is divisible by any of the first twelve numbers, 7 only excepted. The cardinal numbers from 1 to 10 inclusive are treated separately in ten distinct chapters. These, with the introductory chapter and an appendix, the principal portion of which is taken up with magic squares, form the whole of the work.

The nature of our author's remarks will be best seen by making a few quotations. Thus in the chapter on Number One, after speaking of the unity of the Godhead and the oneness of self, he goes on to say:—

"Geography and natural history abound in words which express the separateness of an object, its isolation, its *one-liness*. Similar to the number 1, and to the pronoun I, there are found in different languages and dialects referring to local separation, the words *i*, *hi*, *ey*, *eye*, *egg* (and here think of the Latin *ego* and the Greek ἐγὼ), *eyot*, *ait*, *inch*, *innis*, *île*, *isle*, *inver*, *insula*, *isola*, *isla*; and connote some of these with the animal *eye* and *egg*, having a similar separation as an island in geography. All the latter have the same meaning, and express a portion of land segregated, cut off from other land and surrounded by water—oneness."

With the above we may compare Shakespeare's use of the word *eye* in the passage—"The ground, indeed, is tawny. With an eye of green in 't" ("Tempest," Act II., sc. 1).

Respecting the celebrated *twos* in profane myth and history, we read in the next chapter:—

"Prominent among these are Romulus and Remus; Brutus and Cassius; and in Irish legend Eber and Airem; concerning whom we are informed that Eber was slain by his brother Airem. He was the hero of the Ivernians, the ancient non-Celtic inhabitants of Ireland. Airem was the ancestor of the Celts who conquered the country."

The Hibbert Lecture, May 1886, is referred to in a footnote as the source from which this Irish version of the story of Romulus and Remus was taken. It is new to us, and will probably be so to most of our readers.

In the chapter on Number Three we are told the origin of the heraldic *fleur de lys*:—

"It was the device of *three* fishes tied together with a ribbon, which formed the *fleur de luce—luce* being the name of the fish; but which was afterwards transfigured into the more elegant emblem of the *fleur de lys*, the flower of the iris, taking the place of the fish, its *three* petals still presenting a trine."

It will be remembered that Justice Shallow, in the opening scene of the "Merry Wives of Windsor," speaking of "the dozen white luces" in his coat, remarks that "the luce is the fresh fish."

To the noble army of circle-squarers we leave the task of refuting the following argument; merely remarking that it may with equal facility be used to disprove the quadrature of the parabola, which has been believed in by all orthodox mathematicians since the time of Archimedes:—

"In a quadrangle, the space may be divided into the minutest squares, leaving no space undivided; but in a circle, every square applied to its periphery will always leave an angular space; and however far the process of smaller angles may be carried, an ultimate undivided space will remain."

Apparently our author is not quite satisfied with this; for in the next paragraph (on p. 47) he proves, in another manner, that the circle cannot be squared. In both proofs, for the words "a circle" we may substitute "any curve, including the parabola," without thereby affecting the argument.

We have never heard of Montrecla, to whom we are referred for an account of attempts to square the circle; but possibly Montucla is meant, who in 1754 published a "History of Researches relating to the Quadrature of the Circle," a second edition of which (by Lacroix) appeared in 1831. This conjecture is strengthened by the fact that our author's list of the principal calculators of π ends with Vega (born in 1754 and murdered in 1802), who obtained its value to 140 decimal places, making no mention of Rutherford and Shanks, who in more recent times pushed on the calculation to 500 and 707 places respectively.

From Chapter VII., which treats of a variety of subjects, including among them "the number of the beast" and the fine distinction between *six* and *half-a-dozen*, we select for comment the following sentence:—

"Six, also, is the least number of the *points of fixature*; so that a body cannot under all circumstances be immovable unless secured (or resisted) at six points."

Having only common-sense to guide us, and being unable to divine what train of reasoning could have led the author to the above conclusion, we should imagine that whenever any two points, A, B, of a body are fixed every other point in the straight line AB is also fixed, so that the body can only rotate round the line AB. Consequently if any third point (not in the straight line AB) is also fixed the body is immovable. Do the words "under all circumstances" imply that the body is immovable even when all *six* of our author's "points of fixature" are in the same straight line? If not, we are at a loss to know what they mean.

The appendix contains among other things a method of filling up magic squares which is said to have been communicated by a Russian mathematician to Prof. Sylvester and by him to a friend of the author. As some portions of the Russian Empire are not very far distant geographically from the land of the Chaldæans, this tradition may have had its origin among the magicians, astrologers, Chaldæans, and soothsayers of the Court of Nebuchadnezzar, to whom magic squares were doubtless well known. We hope Mr. Hopkins will be able to trace it to its source; even though it would take some time to do so, and the appearance of a second edition of "The Cardinal Numbers" might thereby be delayed. The public need not be impatient, for they can in the meantime allay their curiosity concerning the properties of magic squares by a perusal of the "Mathematical Recreations" of Ozanam and a host of more modern writers.

OUR BOOK SHELF.

The Romance of Mathematics. Being the Original Researches of a Lady Professor of Girtham College in Polemical Science, with some Account of the Social Properties of a Conic; Equations to Brain-Waves; Social Forces; and the Laws of Political Motion. By P. Hampson, M.A., Oriel College, Oxford. (London: Elliot Stock, 1886.)

OUR first acquaintance with the title, which we have copied in full, was limited to its four opening words. These suggested various ways in which the subject might be treated; we had no idea that the task before us was to examine and report upon a somewhat mild *jeu d'esprit*.

The editor, who poses as a Cambridge student and quondam pupil of the Girtham Professor, and subsequently as her husband, discovers, in a well-worn desk, certain lectures, essays, and other matter. In his introduction he says it is not his intention to disclose how he came into possession of the papers; in the closing pages he is caught in his work of reading and transcribing, and "at length we gained our point, and obtained the full sanction of the late Lady Professor of Girtham College to publish her papers." "Thus her obedient pupil is enabled to repay his late instructress for all her kindness to him," and also to remove from the mind of the reader the unpleasant feeling he has all along had whilst perusing the papers, that he was a party to a mean action in so doing.

The earliest essay, in an unfinished form, written whilst *in statu pupillari*, is entitled "Some Remarks of a Girtham girl on Female Education," and combats those "male sycophants" who "would prevent us from competing with you; you would separate yourselves on your island of knowledge, and sink the punt which would bear us over to your privileged shore. Of all the twaddle—forgive me, male sycophants!—that the world has ever heard, I think the greatest is that which you have talked about female education."

The second paper is a "Lecture on the Theory of Brain-Waves, and the Transmigration and Potentiality of Mental Forces." She takes the usual equation

$$y = \frac{a}{r} \sin \frac{2\pi}{\lambda} (vt - r),$$

and determines λ by the method of mesmerism. "We find the ratio of brain to brain—the relative strength which one bears to another; and then, by an application of our formula, we can actually determine the wave of thought, and read the minds of our fellow-creatures. An unbounded field for reflection and speculation is here suggested. Like all great discoveries, the elements of the problem have unconsciously been utilized by many who are unable to account for their method of procedure. . . . The development of this theory of brain-waves may be of great practical utility to the world. It shows that great care ought to be exercised in the domain of thought, as well as that of speech." Some verses follow, and then we have Papers iii. and iv., which are, in our opinion, the best part of the book, viz. a "Lecture on the Social Properties of a Conic Section," and the "Theory of Polemical Mathematics." Paper v. contains a "Lecture upon Social Forces, with some Account of Polemical Kinematics," and Paper vi. carries on the preceding into "Polemical Statics and Dynamics"; Paper vii. expounds the "Laws of Political Motion," and Paper viii. closes the book with a lecture "On the Principle of Polemical Cohesion." We ought to apologize for going into such detail, but our account will show our readers that the present work does not deal with mathematical discoveries. It is a "skit," with the perusal of which a reader acquainted with mathematics may while away, not unpleasantly, an odd half-hour or two.

Antipodean Notes. By "Wanderer." (London: Sampson Low, 1888.)

Lights and Shadows of Melbourne Life. By John Freeman. (Same publishers.)

THE "notes" in the first of these two books do not embody the results of a very wide experience. They simply record some observations made by the author in the course of a nine months' tour round the world. "Wanderer" does not, however, pretend to offer an exhaustive account of any of the subjects on which he touches. He has an easy, pleasant style, and gives with some vividness his first impressions of the scenes he describes. The greater part of the book relates to New Zealand, the practical, commercial, and social aspects of which he had, he thinks, more and better opportunities of studying than are obtainable by the majority of "globe-trotters." There is a short but interesting chapter on the Maoris, of whose qualities, as they have been affected by contact with civilization, "Wanderer" has no very exalted opinion. He admits, however, that there are exceptions to what he calls "the average of uselessness." One of the native members of the House of Representatives is, he says, "highly educated, intelligent, and even eloquent." The question whether women should be admitted to the House was lately discussed, and the speech of this deputy on the subject was "by far the most brilliant and entertaining of a debate in which many colonial legislators soared above the ordinary level of dull mediocrity."

The second book consists of a series of papers, some of which were originally contributed to Melbourne newspapers. They are written in rather too "smart" a style, but contain much information which it would be hard for Englishmen who may be interested in Melbourne to find elsewhere. The book will no doubt be welcomed by many visitors who will go this year to Melbourne to see the Centennial International Exhibition.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Salt Industry in the United States.

I CAN sympathize to a great extent with your correspondent George P. Merrill on the question of salt statistics. For a number of years I have been accumulating information on the whole subject of salt, and have found the greatest difficulty in obtaining much of a trustworthy character. The most extensive salt literature is in Germany: even there the statistical part of the subject is not dealt with so extensively as the geological, geographical, chemical, and manufacturing. Perhaps the most complete salt literature is that of India, which is issued yearly by the Government; but it deals almost exclusively with Indian salt.

I am not much surprised that the information in our Encyclopædias respecting the salt industry of the United States should be so scanty. Most of the information derivable respecting it has to be obtained from public newspapers, trade pamphlets, or papers in scientific journals. It is true that, so far as the deposit of Petit Anse, in Louisiana, is concerned, the United States Government published an account of it shortly after the termination of the great war. Dr. Sterry Hunt, whom I had the pleasure of meeting at Manchester at the British Association, has written probably more than anyone else on American salts; but it must be borne in mind that it is only within the last twenty years that the great salt discoveries in Western New York and Michigan have been made. I have a complete or nearly complete list of all the Michigan works, which was issued in the *Chicago Tribune* of January 24, 1888. I have also before me a copy of the *Saginaw Courier* of December 18, 1887. This gives some valuable tables respecting the Michigan salt. In Michigan, in 1887, 3,944,309 barrels of salt were inspected by the salt inspector. In 1869, only 561,288 barrels were made; and in 1880, 2,676,588. There was more salt made in Michigan in 1887 than had been made previously to 1869 in that State. The growth of the salt manufacture has been exceedingly rapid in the States; hence the reason why so little is known of it outside the persons interested in the trade.

Within the last five or six years there has grown up a most extensive salt manufacture in the Wyoming Valley in Western New York. Already this new district bids fair to cut out entirely the old Syracuse or Onondaga district. The make of American salt has much more than doubled itself in the last ten years. I am sure that personally I shall be much pleased if Mr. Merrill will, either through your columns or direct to me, give any information more accurate than is obtainable from our Encyclopædias. I am striving to establish at Northwich, the centre of the Cheshire salt trade, a Salt Museum, and although I have been for a long time accumulating specimens of salt from all parts, and have, thanks to the East Indian Government, and through the kind exertions of Mr. J. T. Brunner, M.P., our Parliamentary representative, who is most handsomely furnishing the Museum, a complete set of specimens of Indian salt, yet I find great difficulty in obtaining works treating on salt, also maps, plans, and diagrams. I trust, by degrees, to have a Museum perfectly unique, I believe.

When I say that until the last two or three years our English salt statistics have not been trustworthy, and that it is only by the indefatigable exertions of Mr. Joseph Dickinson, H.M. Inspector of Mines, assisted by myself and one or two other gentlemen connected with our salt trade, that they are now very nearly complete, Mr. Merrill must not be surprised at the difficulty of getting trustworthy information. For some seventeen years I have kept a complete list of all salt exports from the Mersey ports, and this list, I think, is the only complete one published, though the Salt Chamber of Commerce here professes to have a list, which it does not issue for public use. Indeed, I regret to say that it is almost impossible to get any assistance or information from this body.

The French Government issues at times a list of salt manufactured or raised from mines. The last I received, viz. 1879, gave, as the production for that year, 283,000 tons of sea salt and 293,000 tons of rock salt.

I shall be glad to give any information I possess to Mr. Merrill, and should be glad if any of your readers could give any information or assistance that would enable me to make as complete as possible the Salt Museum we are here forming.

Northwich, Cheshire. THOMAS WARD.

Prof. Rosenbusch's Work on Petrology.

PROF. BONNEY'S letter (NATURE, vol. xxxvii. p. 556) makes me venture once more to ask permission for space for a few remarks. One of the objects I had in view in writing to you at first is partly attained by the appearance of Prof. Bonney's "friendly protest"; and his remark that but for my letter he should have refrained "for a season" leads me to hope that in due course this object may be still further realized.

Prof. Bonney sees great objections to Rosenbusch's system of classification, and demurs to some of his groups altogether, both as to those admitted and those omitted. Naturally, then, he desires that this system shall not, by students of petrology, be too readily accepted nor too blindly followed. I do not think there is much danger of this, nor do I think that the "viaduct" was too much complimented either by Dr. Hatch or myself, the defective foundation of the piers in question being quite sufficiently alluded to for the time being.

The position, however, seems to be this. The number of earnest students of petrology is larger now than formerly, and is on the increase. They feel that no satisfactory system of classification had yet been offered to them, and indeed are rather bewildered by the fact that opinions as to what is the best system have been almost as many in number as the teachers who could by any means claim to be authorities entitled to instruct in this matter. Also, it is now a long time since any detailed system of classification, covering the whole ground, has been attempted.

Now we have such an attempt offered to us by Rosenbusch, and there is no doubt that to many it will be very welcome and will be largely used, in spite of the defects undoubtedly seen in it.

Prof. Bonney objects to the viaduct because of the weakness of some of its piers, and still more strongly objects to it, I think, because he considers that when a student has crossed it he will arrive at a point from which he will obtain a view of the surrounding country which will not be a good or correct view, and which will in some respects confuse the knowledge of that country already obtained and still to be sought for.

Would not this be just exactly the best time for some authority of great experience to come forward and point out to us younger workers wherein the viaduct is defective, and wherein we shall see wrongly from the ground on the further side of it; and to tell us his opinions as to a better viaduct, so placed as to lead us to a better point of outlook?

May we hope that Prof. Bonney will himself give us such a detailed criticism of the subject? It would be received with great attention and gratitude by many who, like myself, are looking for "light and leading" in this branch of study.

A. B.

History of the Contraction Theory of Mountain Formation.

IN his "Physical Geology," second edition, p. 674, Prof. Green says: "The notion that the earth's contraction has been the cause of the displacement of the rocks and the elevations of the surface seems to have occurred first to Descartes (éd. française, 1668, p. 322)."

It does not seem to be generally known that, a few years later, the same idea occurred to Newton. In a letter to Dr. Thomas Burnet he refers to that writer's "Sacred Theory of the Earth," the Latin edition of which was published in 1681, and considers the creation of the earth in connection with the Mosaic account. After suggesting illustrations of the "generation of hills," Newton concludes thus: "I forbear to describe other causes of mountains, as the breaking out of vapours from below before the earth was well hardened,—*the settling and shrinking of the whole globe after the upper regions or surface began to be hard;*" though he adds, "I have not set down anything I have well considered, or will undertake to defend."

The letter, which is written in reply to one of Burnet's, dated January 13, 1680-81, is given in full in Brewster's "Memoirs of Sir Isaac Newton," vol. ii. Appendix 4. The manuscript from which it is printed is a copy of the letter, without date or signature; but, according to Brewster, "the whole is distinctly written in Sir Isaac's hand." CHARLES DAVISON.

Birmingham, April 23.

Lightning and Milk.

EMIN PASHA (NATURE, vol. xxxvii. p. 583) mentions the African superstition "that fire kindled by a flash of lightning cannot be extinguished until a small quantity of milk has been poured over it." This idea is embodied in a Russian proverb, and has also existed in parts of Germany (Boyes, *Lacon*, p. 157). Emin Pasha adds that, in tempering swords made from meteoric iron (*vulgo*, thunderbolts), the blacksmith uses not water, but milk. Are other instances of this custom known? Has any explanation been offered? Indian folk-lore furnishes two ideas which may illustrate it: one, that the fall of a meteor is a bad omen (*Indian Notes and Queries*, July 1887, 674); the other, that evil spirits are very fond of fresh milk (*ib.*, December 1886, 198). Meteorites and lightning are connected in the minds of ignorant people, particularly, as Emin Pasha tells us, in the present instance. The milk, therefore, whether applied by smith or fire-man, may be rather intended as a propitiation than used for its intrinsic power of tempering steel or extinguishing flame. F. A. BATHER.

20 Campden Hill Road, Kensington, W., April 29.

The Duplex Pendulum Seismograph.

As the accuracy of the duplex pendulum seismograph has been impugned by a writer in NATURE, vol. xxxvii. p. 571, who at the same time adopts the instrument (with modifications which are, in my opinion, the reverse of improvements) I forward to you comparison diagrams. They show side by side the record given by the seismograph itself, and the real motion of the base of the instrument when that was artificially shaken in a manner that closely imitated an earthquake. The real motion was recorded by means of a multiplying lever hinged by a universal joint in a bracket fixed to a separate support. In both records the motion is magnified about six times. The agreement of the two demonstrates the accuracy of the instrument as an earthquake recorder, alike for large and for small motions. These are examples of tests which I have been in the habit of applying to seismographs since 1880 (see Proc. R. S., vol. xxxi. p. 440). In the present case the test was made with one of the duplex pendulum seismographs made and sold by the Cambridge Scientific Instrument Company, and described by me in NATURE, vol. xxxiv. p. 343. J. A. EWING.

University College, Dundee, April 20.

Self-Induction.

I HAVE to apologize for erroneously attributing to Dr. Lodge a suggestion with reference to the self-induction of wires for high-tension electric discharges. I do not, however, consider, as Prof. Lodge appears to do, that for such discharges it is "on the face of it absurd" to suppose that the self-induction of iron wires is less than that of copper wires of the same dimensions. Prof. Ewing has suggested that for very small values of the magnetizing force, H, iron may possibly behave as a diamagnetic body, and the corresponding values of the magnetic susceptibility, k, may be negative. The values of the magnetic induction, B, which are given by the equation—

$$B = (1 + 4\pi k)H,$$

will be less than H, because k is negative. The rate of increase of B with H will be less than unity for iron if this supposition is true, and will be equal to unity for copper, for which we may suppose that the value of k is negligible. The coefficient of self-induction, which will be proportional to the rate of increase of B with regard to H for wires of the same dimensions will accordingly be less for the iron than for the copper.

City and Guilds Institute, May 2. W. E. SUMPNER.

SUGGESTIONS ON THE CLASSIFICATION OF THE VARIOUS SPECIES OF HEAVENLY BODIES.[1]

IV.

IV.—ON THE SPECTRA OF STARS OF GROUP II.

IN the previous part of this memoir I have attempted to give a general idea of that grouping of celestial bodies which in my opinion best accords with our present knowledge, and which has been based upon the assumed meteoric origin of all of them.

I now proceed to test the hypothesis further by showing how it bears the strain put upon it when, in addition to general grouping, it is used to show us how specific differences are arrived at.

I. GENERAL DISCUSSION OF DUNÉR'S OBSERVATIONS.

In the paper communicated to the Royal Society on November 17 I pointed out that the so-called "stars"

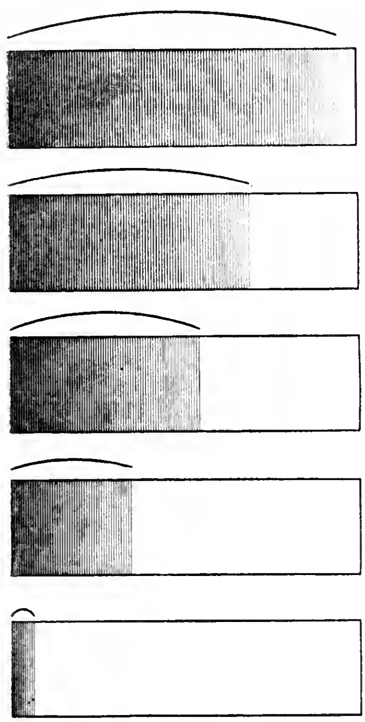

FIG. 6.—Diagram showing how an absorption fluting varies in width according to the quantity of absorbing substance present.

of Class III.*a* were not masses of vapour like our sun, but swarms of meteorites; the spectrum being a compound one, due to the radiation of vapour in the interspaces and to the absorption of the light of the red- or white-hot meteorites by vapours volatilized out of them by the heat produced by collisions.

I also showed that the radiation was that of carbon vapour, and that some of the absorption was produced by the chief flutings of Mn and Zn.

Dunér in his map gives eleven absorption bands, chiefly flutings, in Class III *a*, but in the case of the tenth and eleventh bands there is some discrepancy between his map and the text, to which reference will be made subsequently. His measurements are of the darker portions of the flutings, speaking generally.

[1] The Bakerian Lecture, delivered at the Royal Society on April 12, by J. Norman Lockyer, F.R.S. Continued from p. 11.

It will be clear at once that in the case of the *dark* flutings the dark bands should agree with the true *absorption* of the vapours, and that when the amount of absorption varies, only that wave-length away from the maximum of the flutings will vary. Thus, the same fluting may be represented as in Fig. 6, according to the quantity of the absorbing substance present.

In the case of the *bright* flutings, however, the dark bands on either side may *in some cases* be produced partly by contrast only, and the brighter and wider the bright flutings are the more they will appear to vary, and in two ways: first, they will dim by contrast when the bright fluting is dimmer than ordinary; and secondly, the one on the side towards which the bright fluting expands from its most decided edge will diminish as the bright fluting expands (see Fig. 7).

There is also another important matter to be borne in mind. As these spectra are in the main produced by the integration of the continuous spectra of the meteorites, the bright flutings of carbon, and the dark flutings produced by the absorption of the continuous spectra by the

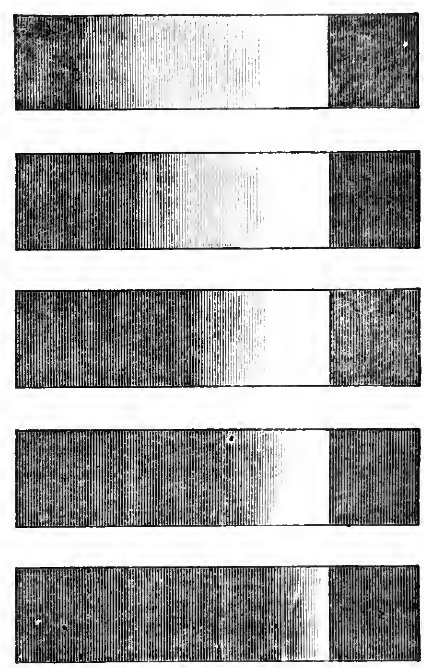

FIG. 7.—Diagram showing the variation in width of a bright fluting, and the consequent variation in width of the contrast band at the fainter edge.

vapour surrounding each meteorite; the proportion of bright fluting area to dark fluting area will vary with the reduction of the spacing between the meteorites.

If any bright or dark flutings occur in the same region of the spectra when the spaces are greatest, the radiation effect will be stronger, and the absorption fluting will be "masked;" where they are least the radiation itself will be masked. This reasoning not only applies to flutings but to lines also.

The Radiation Flutings.

We will first deal with the radiation flutings—those of carbon. The brightest less refrangible edge of the chief one is at wave-length 517, where it sharply cuts off the tail end of the absorption of the magnesium fluting the darkest edge of which begins at 520, as the carbon light from the interspace pales the absorption. The same thing happens at the more refrangible edge of the other absorption of Mg at 500, as Dunér's figures show.

	Less refrangible edge.	More refrangible sharp edge.
Band 8 (absorption of Mg)	502	496 in α Herculis.
	501	496 in ρ Persei.
	503	496 in R Leonis Min.
	505	496 in β Pegasi.

If this explanation of the rigidity of the less refrangible edge may be accepted, it is suggested that the rigidity of the end of band 8 at 496, near the nebula line 495, seems to indicate that we may have that line as the bright, less refrangible, boundary of another radiation fluting.

The fluting at 517 is the chief radiation fluting of carbon. The next more refrangible one, which would be most easily seen, as the continuous spectrum would be less bright in the blue, has its less refrangible and brightest edge at 474.

This in all probability has been seen by Dunér, though, as before stated, there is here a discrepancy between his maps and his text. It lies between his dark bands 9 and 10, the measurements of which are as follow:—

	Less refrangible edge.	More refrangible edge.
Band 9	482	476 in α Orionis.
	484	477 in β Pegasi.
Band 10	472	460 in α Orionis.
	474	462 in α Herculis.

It is not necessary for me to point out the extreme and special difficulty of observations and determinations of wave-lengths in this part of the spectrum. Taking this into consideration, and bearing in mind that my observations of the chemical elements have shown me no other bands or flutings in this region, I feel justified in looking upon the narrow bright space between bands 9 and 10 as an indication of another carbon fluting—the one we should expect to find associated with the one at 517, with its bright edge at 473 instead of 476, where Dunér's measurements place it. There is a bright fluting in this position in Nova Orionis.

I shall refer to both these points later on.

The third fluting, the carbon one with its brightest edge at 564, is certainly also present; though here the proof depends upon its masking effect, and upon the manner in which this effect ceases when the other flutings narrow and become faint.

In addition to these three flutings of carbon, which we shall distinguish in what follows as carbon A, there is sometimes a fourth more refrangible one beginning at wave-length 461, which is due to some other molecular form of carbon. It extends from wave-length 461 to 451, and, as we shall presently see, it is this which gives rise to the apparent absorption band No. 10 in the blue; this we shall distinguish as carbon B.

It is very probable also that in some cases there is, in addition to carbon A and carbon B, the hydrocarbon fluting which begins at wave-length 431, the evidence of this being Dunér's apparent absorption band 11. It may be remarked here, that although most of the luminosity of this fluting is on the more refrangible side of 431, there is also a considerable amount on the less refrangible side.

With regard to bands 9, 10, and 11, then, there is little doubt that they are merely dark spaces between the bright blue flutings of carbon, and that whether they are seen or not depends upon the relative brightnesses of the carbon flutings and the continuous spectrum from the incandescent meteorites. When the continuous spectrum is faint, it will not extend far into the blue, and the resulting dark space between the bright carbon A fluting at 474 and the end of the continuous spectrum is the origin of the apparent absorption band 9. When the continuous spectrum gets very bright, band 9 should, and does, disappear. On reference to the maps of the spectra of the "stars" with bright lines, it will be seen that the broad apparent absorption band in the blue agrees exactly in position with band 9, and it undoubtedly has the same origin in both cases. This band may therefore be regarded as the connecting link between the bodies belonging to Group I. and those belonging to the group under consideration.

Band 10 is the dark space between the bright carbon A fluting at 474 and the carbon B at 461, and can only exist as long as the carbon flutings are brighter than the continuous spectrum. Dunér's mean values for the band are 461–473, and on comparing these with the wave-lengths of the carbon flutings (see Fig. 10, which will be given in the next instalment) it will be seen that the coincidence is almost perfect.

There is a little uncertainty about band 11, which Dunér was only able to measure in one star, but it very probably has its origin in the dark space between the bright carbon B fluting and the hydrocarbon fluting at 431 (see Fig. 10). This would give a band somewhat broader and more refrangible than that shown in Dunér's map; but, as already pointed out, great accuracy in this part of the spectrum cannot be expected.

Chemical Substances indicated by the Absorption Flutings and Bands.

I may state that I have now obtained evidence to show that the origin of the following *absorption* flutings is probably as under:—

No. of Fluting.	Origin.	Wave-length of darkest most refrangible edge.	Wave-length of less refrangible end, given by Dunér as measured in α Orionis.
2	Fe	616	628
3	Mn (2) ...	585	595
4	Mn (1)[1] ...	558	564
5	Pb (1)[2] ...	544	550
6	Ba[3]	524	526
7	Mg	521	517
8	Mg	500	495

These flutings are characteristic of the whole class, and Dunér's catalogue consists chiefly of a statement of their presence or absence, or their varying intensities, in the different stars.

He gives other bands and wide lines which he has measured specially in α Orionis. I have also discovered the origin of the majority of these. They are as follows:—

			Wave-length.
	I.	Fluting of Cr (1)	581
	II.	?	570–577
	III.	Fluting of Pb (2)	567
	IV.	?	543
	V.	Line of Mn seen in bunsen ...	538–540
	VI.	Band of Ba	532–534
Lines	1.	Fluting of Cr (2)...	559[4]
	2.	,, ,, (3)...	536
	3.	Line of Cr seen in bunsen	520
	4.	Ba band	514[5]
	5.	1st, 2nd, and 3rd Ba flutings ...	601
	6.		634
	7.		649

Band 1, which extends from wave-length 649·5 to 663·8, has not yet been allocated.

Tests at our Disposal.

In order to prove that my explanation of the nature of these celestial bodies is sufficient, a discussion of the individual observations of them, seeing that differences in

[1] Means strongest fluting.

[2] The second Pb band has been seen in α Scorpii and α Orionis. Owing to an error in the map in the former paper, this fluting was ascribed to zinc.

[3] This is the second brightest band, wave-length 525. The first, at wave-length 515, is masked by the radiation fluting at 516.

[4] This is not given by Dunér. It would be masked by the Mn fluting in the star. I have inserted it to show that we could not be dealing with the 3rd fluting of Cr at 536 if we could not explain the apparent absence of the 2nd.

[5] In the early stages this band is masked by the vivid light coming from the carbon in the interspaces.

the spectra are known to exist, should show that all the differences can be accounted for in the main by differences in the amount of interspace; that is to say, by a difference between the relative areas of space and meteorite in a section of the swarm at right angles to the line of sight. I say in the main, because subsequent inquiry may indicate that we should expect to find minor differences brought about by the beginnings of condensation in large as opposed to small swarms, and also by the actual or apparent magnitudes of the swarms varying their brilliancy, thus enabling a more minute study to be made of the same stage of heat in one swarm than in another.

How minor differences may arise will be at once seen when we consider the conditions of observation.

The apparent point of light generally seen is on my view produced not by a mass of vapour of more or less regular outline and structure, but by a swarm of meteorites perhaps with more than one point of condensation.

An equal amount of light received from the body may be produced by any stage, or number of nuclei, of condensation; and with any differences of area between the more luminous centre and the outliers of the swarm.

All these conditions producing light of very different qualities are integrated in the image on the slit of the spectroscope.

I have said "generally seen," because it has been long known that many of the objects I am now discussing are variable, as well as red, and that at the minimum they are not always seen as sharp points of light[1] but have been described as hazy.

The severe nature of the tests at our disposal will be recognized when we inquire what must follow from the variation of the spacing. Thus, as the spacing is reduced—

I. The temperature must increase.

- *a.* Vapours produced at the lowest temperatures will be the first to appear.
- *β.* The spectrum of each substance must vary with the quantity of vapour produced as the temperature increases, and the new absorptions produced must be the same *and must follow in the same order* as those observed in laboratory experiments.

II. The carbon spectrum must first get more intense and then diminish afterwards as the spaces, now smaller, are occupied by vapours of other substances.

- *a.* The longest spectrum will be that produced by mean spacing.
- *β.* The masking of the dark bands by the bright ones must vary, and must be reduced as the mean spacing is reduced.

III. The continuous spectrum of the meteorites must increase.

- *a.* There will be a gradually-increasing dimming of the absorption-bands from this cause.
- *β.* This dimming will be entirely independent of the width of the band.

IV. The spectrum must gradually get richer in absorption-bands.

- *a.* Those produced at the lowest temperatures will be relatively widest first.
- *β.* Those produced at the highest temperatures will be relatively widest last.
- *γ.* They must all finally thin.

These necessary conditions, then, having to be fulfilled, I now proceed to discuss M. Dunér's individual observations. I shall show subsequently that there are, in all probability, other bodies besides those he has observed which really belong to this group.

[1] Hind first noticed this in 1851. Quoted by Arago, "Astronomie Populaire."

II. Discussion of Dunér's Individual Observations.

Consideration of the Extreme Conditions of Spacing.

Cæteris paribus, when the interspaces are largest we should have a *preponderance* of the radiation of carbon, so far as quantity goes. The bands will be wide and pale, the complete radiation will not yet be developed; a minimum of metallic absorption phenomena—that is, only the flutings of magnesium (8 and 7), the first fluting of manganese (3), and the first fluting of iron (2); but the great width of the bright band at 517 will mask band 8.

When the interspaces are least, the radiation of carbon should give place to the absorption phenomena due to the presence of those metallic vapours produced at the highest temperature at which a swarm can exist as such; the bright flutings of carbon should be diminished, and the true absorption flutings of Mg, Fe, Mn, Pb, and the band of Ba, should be enhanced in intensity.

There will be an *inversion* between the radiation and absorption.

The highest intensity of the absorption phenomena will be indicated by the strengthening of the bands 2, 3, 4, 5, and 6; and the appearance of the other flutings and bands specially recorded in *a* Orionis. The bands 7 and 8 will disappear as they are special to a low temperature, and will give way to the absorption of manganese, iron, *b*, &c.

This inversion, to deal with it in its broadest aspect should give us at the beginning 7 strong, and 2, 3 weak, and at the end 7 and 8 weak, and 2, 3 strong.

The first stage, representing almost a cometic condition of the swarm before condensation has begun, has been observed in Nos. 3,[1] 23, 24, 25, 36, 68, 72, 81, 118, 247, 249. There is a very large number of similar instances to be found in the observations. The above are only given as examples.

The *last* stage, before all the bands fade away entirely, has been observed in Nos. 1, 2, 26, 32, 33, 38, 40, 61, 64, 69, 71, 75, 77, 82, 96, 101, 116. As before, these are only given as instances.

It is natural that these extreme points along the line of evolution represented in the bodies under consideration should form, as I think they do, the two most contrasted distinctions recorded by Dunér—that is, recorded in the greatest number of cases.

Origin of the Discontinuous Spectrum.

I have already shown that when the meteorites are wide apart, though not at their widest, and there is no very marked condensation, the spectrum will extend farther into the blue, and therefore the flutings in the blue will be quite bright; in fact, under this condition the chief light in this part of the spectrum, almost indeed the only light, will come from the bright carbon. Under this same condition the temperature of the meteorites will not be very high, there will therefore be little continuous spectrum to be absorbed in the red and yellow. Hence we shall have discontinuity from one end of the spectrum to the other. This has also been recorded, and in fact it is the condition which gives us almost the most beautiful examples of the class (196, *a* Herculis, 141, 172, 229).

The *defect* of continuous light *in the blue* in this class, after condensation has commenced and the carbon flutings are beginning to disappear, arises from defect of radiation of the meteorites, and hence in all fully-developed swarms the spectrum is not seen far into the blue for the reason that the vapours round each meteorite are at a tempera-

[1] The references are to the numbers of the stars in Dunér's catalogue.

ture such that fluting absorption mainly takes place, although of course there must be some continuous absorption in the blue. This is perhaps the most highly-developed normal spectrum-giving condition; 44, 45, 55, 60, 65, 86, 92, 278 are examples.

The Paling of the Flutings.

Subsequently, the spectra are in all cases far from being discontinuous, and the flutings, instead of being black, are pale. Thus, while the bands are dark in the stars we have named, they are not so dark in α Orionis. Here, in short, we have a great distinction between this star and α Herculis, *o* Ceti, R Lyræ, and ρ Persei.

Obviously this arises from the fact that the average distances between the meteorites have been reduced; their temperature being thereby increased as more collisions are possible, the vapours are nearly as brilliant as the meteorites, and radiation from the interspaces cloaks the evidences of absorption. Nor is this all: as the meteorites are nearer together, the area producing the bright flutings of the carbon is relatively reduced, and the bands 10 and 9 will fade for lack of contrast, while 8 and 7 will fade owing to the increased temperature of the system generally carrying the magnesium absorption into the line stage; *b* is now predominant (see 102, 157, 163, 114, 125, 135).

Under these conditions the *outer* absorbing metallic atmosphere round each meteorite will in all probability consist of Mn and Fe vapours, and in this position the masking effect will least apply to them. This is so (114, 116); they remain dark, while the others are pale.

Here we have the indication of one of the penultimate stages already referred to.

Phenomena of Condensation.

Dealing specially with the question of condensation,—I have already referred to possibly the first condition of all, recorded by Dunér in the observations now discussed—I may say that the first real and obvious approach to it perhaps is observed when all, or nearly all, except 9 and 10 of the flutings are *wide* and *dark*. The reasons will be obvious from what has been previously stated. Still more condensation will give all, or nearly all, the bands wide and pale, while the final stage of condensation of the swarm will be reached when all the bands fade and give place to lines. We have then reached Class II. (107, 139, 168, 264); 2 and 3 should be and are perhaps the last to go (203).

The Bands 9 and 10.

With regard specially to the bands 9 and 10, which include between them a bright space which I contend is the second fluting of carbon, I may add that if this view is sound, the absence of 10 should mean a broad carbon band, and this is the condition of non-condensation, though not the initial condition. The red flutings should therefore be well marked—whether broad or not does not matter; but they should be dark and not *pale*. Similarly the absence of band 9 means non-condensation.

Therefore 9 and 10 should vary together, and as a matter of fact we find that their complete absence from the spectrum, while the metallic absorption is strong, is a very common condition (1, 2, 6, 16, 26, 32, 39, 40, 46, 54, 60).

That this explanation is probably the true one is shown by further consideration of what should happen to the red flutings when 9 and 10 are present. As the strong red flutings indicate condensation, according to my view this condensation (see *ante*) should pale the other flutings. This happens (3, 8, 13, 28, 35, 45, 30; and last, not least, among the examples, I give 50, α Orionis).

III. Results of the Discussion.

The Line of Evolution.

I have gone over all the individual observations recorded by Dunér, and, dealing with them all to the best of my ability in the light afforded by the allocation of the bands to the various chemical substances, the history of the swarms he has observed seems to be as follows:—

(1) The swarm has arrived at the stage at which, owing to the gradual nearing of the meteorites, the hydrogen lines, which appeared at first in consequence of the great tenuity of the gases in the interspaces, give way to carbon. At first the fluting at 473 appears (as in many bright-line stars), and afterwards the one at 517. This is very nearly, but, as I shall show subsequently, not quite, the real beginning of Class III.*a*, and the radiation is now accompanied by the fluting absorption of Mg, Fe, and Mn—bands 7, 2, 3. This is the absorption produced at the temperature of the oxy-coal gas flame, while the stars above referred to give us the bright line of Mn seen at the temperature of the bunsen.

(2) The bright band of carbon at 517 narrows and unveils the Mg absorption at band 8. We have 8 now as well as 7 (both representing Mg), added to the bands 2 and 3, representing Fe and Mn, and these latter now intensify.

(3) The spacing gets smaller; the carbon, though reduced in relative quantity, gets more intense. The second band at 473 in the blue gets brighter as well as the one at 517. We have now bands 9 and 10 added. This reduced spacing increases the number of collisions, so that Pb and Ba are added to Mg, Fe, and Mn. We have the bands 2, 3, 4, 5, 6, 7, 8, 9, and 10. This is the condition which gives, so to speak, the normal spectrum

(4) This increased action will give us a bright atmosphere round each meteorite, only the light of the meteorite in the line of sight will be absorbed: we shall now have much continuous spectrum from the interspaces as well as the vapour of carbon. *The absorption flutings will pale*, and the Mg flutings will disappear on account of the higher temperature, while new ones will make their appearance.

(5) Greater nearness still will be followed by the further dimming of the bright carbon flutings including the one at 517. The blue end of the spectrum will shorten as the bands fade, narrow, and increase in number. If the star be bright, it will now put on the appearance of α Orionis; if dim, only the flutings of Fe and Mn(1), bands 2 and 3, will remain prominent.

(6) All the flutings and bands gradually thin, fade, and disappear. A star of the third group is the result.

In the latter higher-temperature stages we must expect hydrogen to be present, but it need not necessarily be visible, as the bright lines from the interspaces may cancel or mask the absorption in the line of sight of the light of the meteorites; but in case of any violent action, such as that produced by another swarm moving with great velocity, we must expect to see them bright, and they are shown bright in a magnificent photograph of *o* Ceti, taken for the Draper Memorial, which I owe to the kindness of Prof. Pickering. I shall return to this question.

Stages antecedent to those recorded by Dunér.

So far I have referred to the swarms observed by Dunér. The result of the discussion has been to show that all the phenomena are included in the hypothesis that the final stages we have considered are antecedent to the formation of stars of Group III., bodies which give an almost exclusively line absorption, though these bodies are probably not yet stars, if we use the term star to express complete volatilization, similar to that observed in the case of our sun.

The question then arises, Are all the mixed fluting stages really included among the objects already considered?

It will be remembered that in my former communication I adduced evidence to the effect that the mixed fluting stage was preceded by others in which the swarms were still more dispersed, and at a lower temperature. The first condition gives us bright hydrogen; the last little continuous spectrum to be absorbed, so that the spectrum is one with more bright lines than indications of absorption; and, in fact, the chief difference between the spectra of these swarms and of those still sparser ones which we call nebulæ lies in the fact that there are a few more bright metallic lines or remnants of flutings; those of magnesium, in the one case, being replaced by others of manganese and iron.

If my view be correct—if there are stages preceding those recorded by Dunér in which we get both dark and bright flutings—it is among bodies with spectra very similar to these that they should be found.

The first stage exhibited in the objects observed by Dunér is marked by flutings 7, 3, and 2 (omitting the less refrangible one not yet allocated), representing the flutings Mg, Mn, and Fe visible at the lowest temperatures.

The stars which I look upon as representing a prior stage should have recorded in their spectra the flutings 7 and 3 (without 2), representing Mg and Mn.

(*To be continued*)

THREE DAYS ON THE SUMMIT OF MONT BLANC.

ALPINE men are already beginning to think of the work of the coming season. We commend to their attention the following notes relating to the experiences of M. Richard, who spent three days during the past summer on the summit of Mont Blanc, with a view to making a series of continuous meteorological and other observations. There are many Alpine men who might, if they pleased, follow his example without much inconvenience to themselves and with considerable advantage to science. The following is a summary of the record which M. Richard has contributed to *La Nature*:—

The summit of Mont Blanc is a station of the utmost importance to meteorology, since it rises to a great height (4810 metres), and overtops the whole Alpine group. But it had not hitherto been considered possible to remain there for any length of time. De Saussure, whose statue is erected at Chamounix, passed some days in 1788, on the Géant hill, at the height of 3510 metres. In 1844 Martins, Bravais, and Le Pileur, pitched their tent at the Grand-Plateau, 4000 metres high, and here they passed several days, and made numerous and important observations. Hitherto no explorer had remained on the summit of the mountain itself for any length of time; tourists making but a very short stay—usually only a few minutes From these facts we can see the importance of the scientific expedition carried out in the summer of 1887, with great success, by M. Joseph Vallot, one of the most daring and able members of the Alpine Club. Having made, in 1886, a series of physiological observations, during the ascent of some of the highest peaks of the Alps, he determined to establish on Mont Blanc three temporary meteorological observatories, the first at Chamounix, 1050 metres high, the second on the rocks of the Grands-Mulets, 3059 metres high, and the third on the summit of Mont Blanc. He constructed meteorological sheds, and furnished each of them with registering instruments constructed by MM. Richard Brothers—a barometer, a thermometer, and a hygrometer. The instruments placed at Chamounix and the Grands-Mulets were inspected every week, but those at the summit could not be reached for fifteen days, on account of bad weather. To superintend the lower stations he procured the assistance of M. Henri Vallot, a distinguished engineer, on whose competence and carefulness he could rely. At Chamounix, M. Joseph Vallot's plan was considered impracticable. He executed it, however, in company with M. F. M. Richard, one of the makers of the registers. No less than twenty-four guides were necessary, on account of

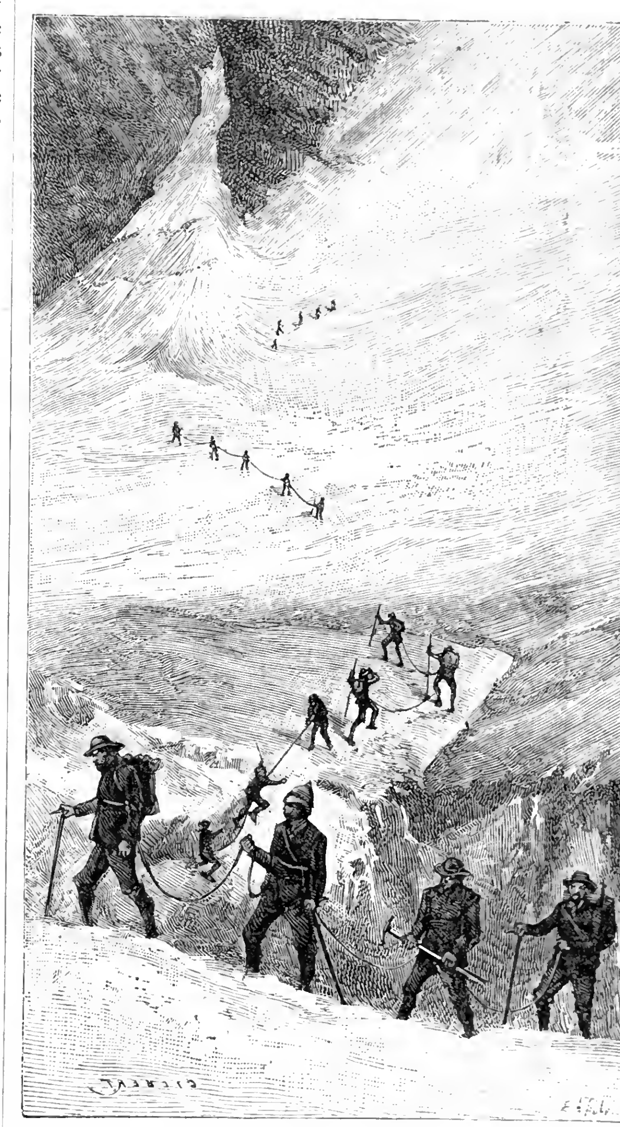

Fig. 1.

the great weight of the baggage (250 kilogrammes). At midday, July 27, 1887, they began the ascent to the Grands-Mulets. On account of the late start, the party, overtaken by night, arrived at the Grands-Mulets at 10 o'clock. Getting to bed at 11 o'clock, the travellers set out again the next morning at 3, after a light meal.

M. Richard then proceeds to tell the story of the journey and of the time spent on the top of Mont Blanc. The ascent from the Grands-Mulets is difficult, but not very dangerous when the snow is good. Crevasses have to be crossed by ladders, and very steep banks of snow must be struggled through. They arrived at the Grand-Plateau at 7 o'clock, and stopped there for refreshment and repose. At the Tournette rock, one of the bearers was forced to stop from fatigue, and to give his load to one of the more robust, and about 3 o'clock in the afternoon they arrived at the summit. All the guides but two deposited their burdens on the snow, and immediately took their departure. When ascending the last hill, MM. Vallot and Richard were attacked by mountain-sickness, and for some hours did not recover. M. Richard compares the shape of the mountain-top to a pear cut in two and resting on a plate, the stalk of the fruit well representing the narrow ridge by which one ascends. Between this ridge and the dome, which measures scarcely more than 20 metres in diameter, is a small indentation, in which they fixed their tent. Having driven the stakes into the snow, they secured the tent by a long rope. None of them had at that time the strength or courage to arrange the baggage. They were compelled to take shelter from the wind, and having refreshed themselves with a little soup, made with melted snow and preserved bouillon, they stretched themselves on the ground, with their heads on the boxes of instruments and the cooking-utensils.

Overcome by his efforts in erecting the tent, M. Richard fell asleep; but during part of the night M. Vallot made gallant efforts to fix his instruments, but he was at length compelled by the snow to return. After some hours of sleep, the cold woke M. Richard, and, fearing the effects of the carbonic acid gas engendered by the breathing of four persons, with the consent of the others he allowed some air to enter, and, lighting a lantern, placed it on the ground, believing it would be extinguished before there would be any danger of suffocation. However, the wind which raged outside kept the tent well ventilated, and froze them to the marrow. About 4 o'clock they all went out of the tent and watched the sun rise—a sight which, M. Richard says, was worth all the pains and fatigues they had endured. The thermometer, when placed on the snow, stood at 19° C. below zero. The sun rose, and it was a most marvellous sight. As the day-star shone out, rosy clouds enveloped the snow-clad tops of the surrounding mountains; little by little, the shadows in which the rocky peaks emerging from the snow were clothed disappeared, leaving the peaks covered with the richest tints. The clouds below sometimes appeared like a rough sea, with its waves dashing against a rocky shore, and sometimes like a thick veil thrown over valleys by the night. Then these clouds dissolved into air under the influence of the sun's rays, seeming to disappear as if by magic, leaving no other trace of their existence than a light mist clinging to the sides of the mountains.

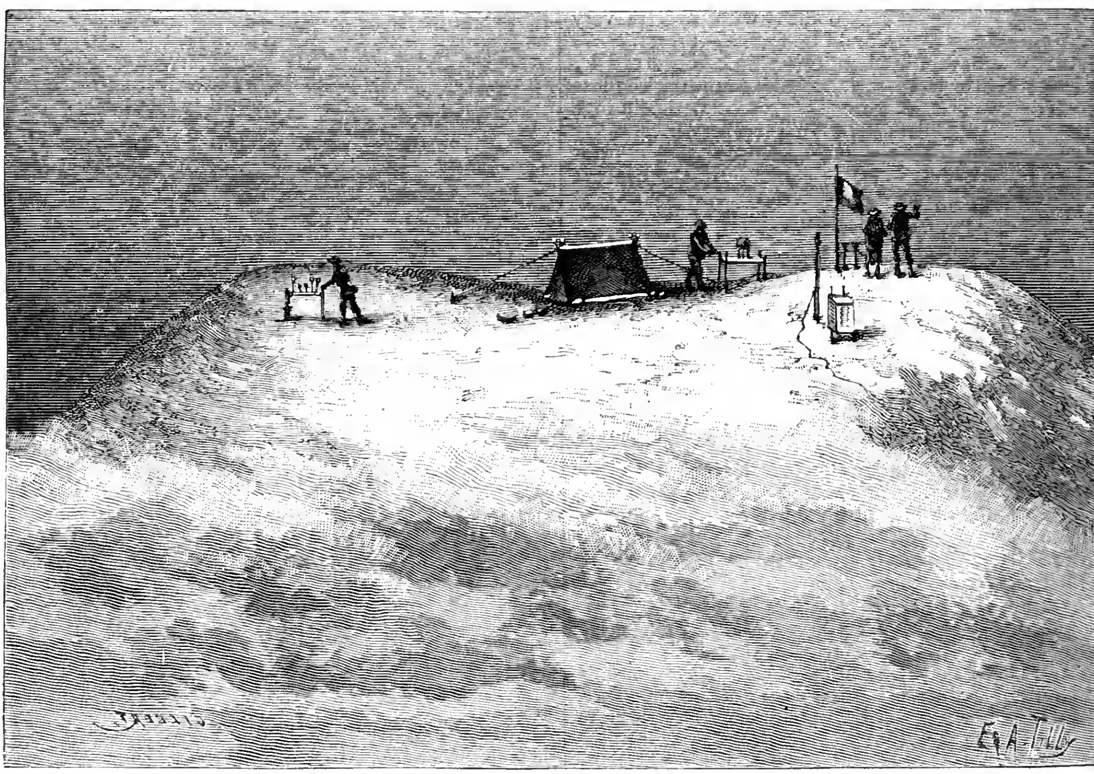

Fig. 2.

They now began to put their instruments into position. The large actinometer, made by M. Violle, was placed on a small table; and the others—the actinometers of Arago and M. Violle, the thermometers, and the Fontin barometer—being fixed (Fig. 2), M. Vallot at once commenced his observations. Then they made their tent more comfortable with a floor of double-tarred cloth, and, above this, a mattress, hard, no doubt, but to them a very welcome addition. The tent was 4 metres square, and 1·50 metre high. The health of the party was not very good: M. Richard and one of the guides suffered from severe headaches, with feverish symptoms. The least effort, even ordinary movement, caused such fatigue that they were compelled to lie down during a great part of the day. They had a visitor the first day, in the person of Baron Munch, coming from Courmayeur, in Italy, into Chamounix, who was amazed to find sojourners on the top of Mont Blanc. The second night was not so trying as the first: they had pillows, which were softer than the pots and pans, and they thus had a most refreshing sleep. The tent was very picturesque. M. Vallot had brought for the party gutta-percha snow-boots, which they put on over fur-lined boots. Thanks to this precaution their feet were kept free from frost-bite. Their leather shoes were of no use; they had been dried in the sun and hung on a string stretched aloft across the tent. On this string at night were also hung the glasses which are always necessary to protect the eyes from ophthalmia in those regions. M. Vallot had also brought coverings for the ears and neck, and linen masks to preserve the skin of the face. Equipped in this manner the aspect of the travellers was curious and even terrifying (Fig. 4). The tent with the various articles hung up, with the boxes of provisions, the blazing stove, and the boiling soup, had a most picturesque appearance (Fig. 3).

The second day was spent in making observations. The provisions were almost neglected; they never had an appetite during their stay. The different preserved meats, though very tempting, did not entice their benumbed stomachs, and twice each day they took nothing but a little preserved bouillon, in which a small piece of cheese had been broken. Their drink was warm coffee; on the first day tea had made them ill, and they never could take it again during their three days' sojourn: the guides, however, drank a little of it.

On July 30, the observations began at sunrise. Towards 10 o'clock the little colony received a second visitor, an Englishman, who, on his departure, wished to take away with him some letters dated from the top of Mont Blanc. A yellow-beaked crow settled herself time after time near the observers. The guides declared that her presence was a sign of good weather; but it did not prove so. Towards 2 o'clock enormous clouds began to form on the side of Mont Pelvoux; then their colour changed; the gloom turned to darkness; and while the weather remained fine over Chamounix, the valley of Aosta and the Savoy Alps were soon hidden by a terrible thunderstorm. A furious wind drove the observers into the tent. It was 4 o'clock, and they had almost made up their

FIG. 4. FIG. 3.

minds to descend, but as there was not time to put all their instruments in safety, they decided to remain and weather the storm. They held the ropes of the tent, and piled snow all around it to keep it steady. Towards 9 o'clock, M. Vallot having gone out, found himself surrounded by electrical clouds, which played around his clothes and his head, but he escaped any actual shock. During the hours that they thus anxiously passed in the tent they were compelled to close the last opening to prevent the snow from getting in. But the time was not spent without profit. M. Vallot made some physiological diagrams. The beatings of the pulse, of the carotid, &c., were to have so much the more interest because they would differ from those which would be obtained when but a short stay is made, the travellers now having been two days at the summit. These observations made them forget their troubles. At last, about 2 o'clock in the morning, the tempest passed away, and, although the wind continued to blow violently, they got a refreshing sleep.

They decided on the following day, July 31, to continue their observations till 9 o'clock, then to bring everything into the tent, and to redescend to Chamounix. The guide Payot was suffering from a violent head-ache, with a high fever, and was compelled to keep his bed, but about 11 o'clock he bravely offered to descend at once, and even desired to carry his knapsack. M. Vallot had not given orders for help to be sent to take their baggage away; they therefore left the greater portion behind them in the tent; still there were many things that could not be left. These were divided into bundles, and, with a last glance at the magnificent view, they began the descent. The guide Michel had warned them that this would be very difficult, since last night's storm would have obliterated all traces of the usual paths. And so it was found to be. After the Grand-Plateau, the journey was most dangerous. At this height it had rained, and the snow had become so soft that they often sank to the waist in it. In the rapid slopes, where they were forced to descend zigzag, the snow slipped from under their feet, but, after much care and fatigue, they arrived at the Grands-Mulets. A good meal, a denser air, and a milder temperature, soon restored them to their usual health. Towards 7 o'clock they came to Chamounix, where they received an enthusiastic welcome.

It had thus been proved that it was quite possible to live and make observations at those high altitudes. The greatest danger is in the violent storms that burst almost without notice, and which may become terrible tempests against which any temporary observatory would not stand. M. Richard says that the results of the observations will be published when the papers have been inspected and classified.

THE PHOTOGRAPHIC CHART OF THE HEAVENS.

WE reprint from the *Observatory* for May the following article by the editors:—

The "Bureau du Comité international permanent pour l'exécution photographique de la Carte du Ciel" has published, amongst other more technical papers relating to this subject, one by Dr. Gill, of a very remarkable character, to which we wish to draw attention. Most of those who attended the Conference understood that the work in contemplation was to make a photographic chart of the heavens, to take pictures of the stars by photography, showing, with the greatest care, the appearance of the heavens as they are at the present time, in order that at a future time these pictures might be used, by comparison with other pictures taken under similar conditions or directly with the sky, to determine the many questions that could be dealt with in this way—to enable, in fact, the astronomer of the future to have the sky of his past and his present to deal with. That this was so will be seen from a consideration of the three following resolutions which were agreed to unanimously by the Conference:—

"1. The progress made in astronomical photography demands that the astronomers of the present day should unite in undertaking a description of the heavens by photographic means.

"2. This work should be carried out at selected stations, and with instruments which should be identical in their essential parts.

"3. The principal objects are (α) to prepare a general photographic chart of the heavens for the present epoch, and to obtain data which will enable us to determine with the greatest possible accuracy the positions and the brightness of all the stars down to a given magnitude (the magnitude being understood in a photographic sense to be defined); (β) to provide for the best means of utilizing both at the present day and in the future the results of the data obtained by photographic means."

These were the fundamental resolutions; others, recommended by the two sections into which the Conference divided, were adopted as explanatory of the first. Amongst these was one in which it was decided to take "a second series of plates down to the 11th magnitude, in order to insure greater precision in the micrometric measurement of the reference-stars, and render possible the construction of a catalogue." We have stated these fundamental resolutions at length as bearing on the question of a catalogue of stars, for the paper by Dr. Gill contains the astounding proposition of cataloguing no less than 2,000,000 stars; that is to say, Dr. Gill gravely and seriously proposes the establishment of a Central Bureau, consisting of chief, assistants, secretaries, and a staff of measurers and computers, to take the photographs and *measure* them, and make a catalogue, the work to go on for twenty-five years at a cost of 250,000 francs, or £10,000, per annnm, or for fifty years at 150,000 francs.

It is quite true that this is only a proposition that Dr. Gill makes; but if such a proposition is possible in face of these direct resolutions of the Conference, it is quite time that everyone interested in the success of the work the Conference met to consider (that is, the photographic chart of the heavens) should bestir himself and see that the proposed work is not endangered by such astounding proposals.

To tack on to a work such as that sanctioned by the Conference—a work eminently practical, that has the support of all astronomers, and that has already been taken up by many of the Governments who were expected to join—a gigantic work such as Dr. Gill proposes, a work beside which that proposed by the Conference sinks into insignificance, would neither be fair to the Conference nor just to those Governments who have joined in the undertaking. The feature of the international scheme that makes it possible to obtain the assent of Government is that the work is proved to be practicable by experiment, and that it can be done at a moderate cost in something like five years, while the results are good for as long as the plates will last. To increase this work by extending it to, at the lowest computation of time, twenty-five and possibly fifty years, and to add enormously to the cost, would be to jeopardize the whole scheme.

Dr. Gill states that the actual state of astronomical science demands a catalogue of stars to the 11th magnitude. He thus raises the question on its merits; and we would here state that it is more than possible that not only is there no need of such a catalogue, but that the use of such catalogues as he proposes has for ever ceased. The minds of some astronomers move in grooves, and it will, no doubt, never be conceded by them that catalogues can be superseded; they will die as they have lived, in the strong belief that the only way to use the stars is to catalogue them.

Till recently the knowledge we had of the stars was only to be gained from a written description of their brightness and position with regard to each other; hence the catalogue was an absolute necessity if we needed to know the number or brightness of certain stars in any part of the sky at any previous time; and we could only find this out if we had a catalogue of that time. Our catalogues of stars are all we have to show what has been observed up to the present time; but when we have a photographic chart of the heavens, we have for our record not a catalogue, but a representation. That catalogues of stars such as are used for fundamental places will be always used goes without saying; the photographic plates themselves, and the four or five stars on each required as the fiducial points and for identification, will of course be catalogued; but, beyond this, to catalogue the stars on each plate, to measure them for the purpose only of getting their places written down, would be the most utter waste of time, labour, and money that it could enter the mind of man to conceive.

The proposition brought forward by Dr. Gill should be settled decisively so far as the proposition concerns the work proposed by the Conference. There can be no question that such a thing was never intended; had such a thing been thought of, we should have had a "Conference for discussing the best way of making a Catalogue of Stars by photography."

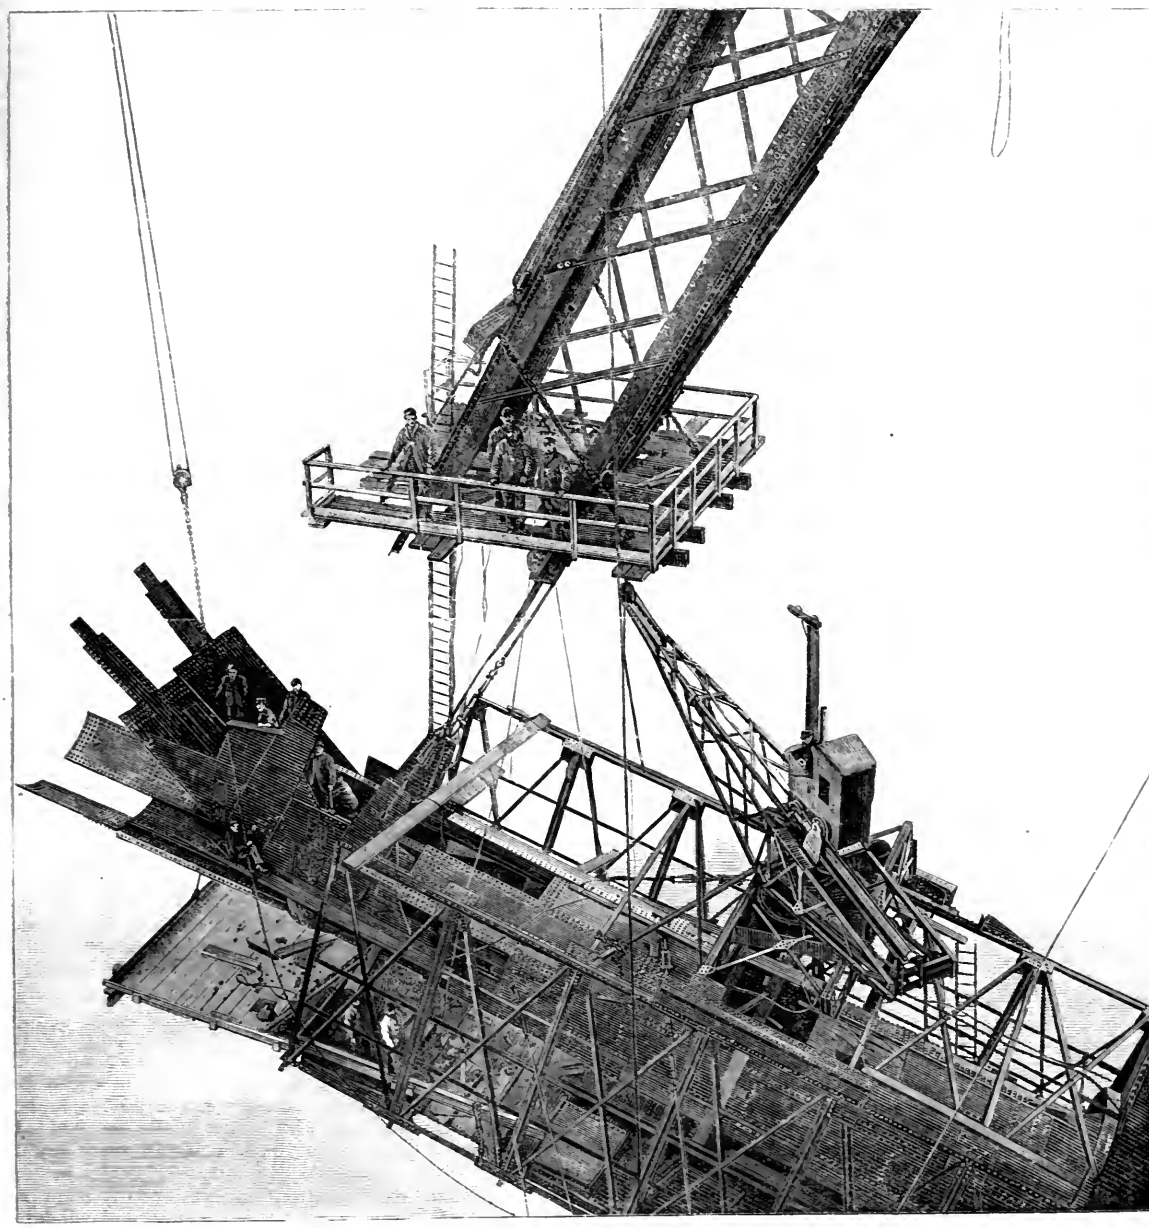
As this was not done, it can be done now; and if there is the great need of a catalogue of stars to the 11th magnitude felt by so many astronomers, as stated by Dr. Gill, it is a thing of so much greater importance as far as cost and time are concerned, that it should be considered and dealt with entirely apart from the other work. A new Congress might discuss it; the one which met in 1887 is not in any way committed to such a scheme.

THE FORTH BRIDGE.

WE have been enabled, through the kindness of Mr. Baker, to reproduce one of the photographs of the Forth Bridge, showing what is known as the "junction" at the end of bay 1, between tie 1, strut 2, and the bottom member.

A general account of the Forth Bridge has been so recently placed before the readers of NATURE (vol. xxxvi. p. 79), in the lecture by Mr. Baker, on May 20, 1887, before the Royal Institution, that it is unnecessary to cover the same ground again. The progress made in erection since that date is indicated by our engraving, showing the successful completion of the lower portion of the first bay.

The junction we have illustrated is nothing more nor



less than the connection of the web of a lattice girder with one of its booms, but here the junction alone weighs as much as an ordinary iron railway bridge of 100 feet span. This mass of steel work is suspended 80 feet above high water, and projects 180 feet beyond the masonry piers. Considerable forces are sometimes needed to bring the tubes into their correct position; and as in the case of the Britannia Bridge, which on a hot day moves 3 inches horizontally and $2\frac{1}{4}$ inches vertically between sunrise and sunset, so here considerable movement takes place during the day, and by careful watching the great tubes can sometimes be caught and retained in proper position, without the intervention of hydraulic or other power.

The weight of steel employed in the junction now under consideration is about 90 tons. The attachments to the strut and tie are made by means of strong gusset plates, the bottom member itself being strengthened internally at the junction by suitable diaphragms.

The importance of this junction will be readily understood, when it is stated that a load of some 6000 tons—the weight of an American liner—will be transmitted through it, in the finished structure, on its way to the masonry pier. Some 16,000 rivets are required for the junction; and large as this number may appear, it bears but a small ratio to the eight million rivets used in the whole structure. The method of construction of the junction was that uniformly adopted in dealing with these members. The junction was erected on the drill roads attached to the workshops at South Queensferry, all holes drilled by specially designed plant; and, having been marked for re-erection, it was taken down and transported plate by plate, and finally hoisted into position in the finished structure from a steam barge, by a crane working from the internal viaduct.

The tie was built downwards from the top of the vertical column; the timber cage—shown in our illustration—in which the men worked being attached to and following it as length by length was added. To design and build a structure of steel to bear a load of some 6000 tons is no mean task in itself, but what shall we say of the whole undertaking, when this junction alone contains but one five-hundredth of the material required for the completed Forth Bridge?

FLORA OF THE ANTARCTIC ISLANDS.

MR. W. B. HEMSLEY, who elaborated at Kew the collections made during the *Challenger* expedition illustrative of the floras of oceanic islands, has handed to me the following interesting letter from Dr. Guppy. The materials and notes accumulated by this skilful observer during his travels in the Western Pacific threw a good deal of light on the mode in which oceanic islands were stocked with plants, and Mr. Hemsley was able to make an advantageous use of them in discussing the collections made in the same region by Prof. Moseley.

I myself am very much impressed with the probable truth of the views expressed by Dr. Guppy. It would be very desirable to obtain additional observations which would serve to test their accuracy. It is with this object that I have obtained Dr. Guppy's permission to communicate his letter to NATURE.

W. T. THISELTON DYER.

Royal Gardens, Kew, April 28.

17 *Woodlane, Falmouth, April* 8, 1888.

As I am likely to be proceeding soon to the South Seas, I have been re-perusing your volume of the "Botany of the *Challenger*," more especially the remarks concerning the dispersal of plants, which I hope to take the opportunity of following up in a more systematic way than before.

I was thinking that if you thought it worth while you might direct the attention of masters of ships going round the Horn and the Cape of Good Hope to the chance of finding seeds in the crops of the oceanic birds that follow the ships in the regions of the westerly winds. I am inclined to believe that important results would be obtained. Judging from my experience, about one bird in twenty-five would contain a seed in its crop.

I am still inclined, if you will pardon my saying so, to the belief that the agency of birds like the Cape pigeons may explain some of the difficulties in the floras of the islands in the Southern Ocean. To return to the instance of my seed, I have since found an account where a Cape pigeon, around the neck of which a ribbon had been tied, followed a ship on its way home from Australia for no less than 5000 miles (Coppinger's "Cruise of the *Alert*," 1885, p. 18); and on consulting other voyages I find that the Cape pigeon appears to perform the circuit of the globe in the region of the Westerlies, so that my seed might readily have been transferred from Tristan d'Acunha to Amsterdam.

A remarkable point has occurred to me whilst reading your remarks (doubtless you have already thought of it). In a botanical sense, and also in a geographical sense, the Antarctic Islands seem to be arranged in two parallel zones. Tristan d'Acunha, Amsterdam, and St. Paul's, lying between the parallels of 37° to 40° S. lat., have similar floras. Further south is the second zone, between 47° and 55° (*circa*), in which the land and islands (Fuegia, Crozets, Kerguelen, Macquarie, &c.) are characterized by their common floras. Now, how are these two parallel botanical zones to be explained? It seems to me that if you grant that the northern zone may largely derive its common characters by the agency of birds following the westerly winds, such as I believe to have been the case, you are almost forced to the conclusion that the floras of Fuegia, Kerguelen, Macquarie Island, &c., in the southern zone have obtained their common characters in the same way. Of course the distinctiveness between the floras of the two parallel zones would then be explained by the difference in the climatic conditions arising from difference in latitude. For my own part I do not think the hypothesis of a sunken southern tract (or tracts) of land to be supported by geological evidence. Is not the geological character of the remote oceanic islands strongly negative of the idea that they are portions of ancient submerged tracts? Can Kerguelen, Amsterdam, &c., be in any sense *continental* islands as regards their rocks? With reference to New Zealand, if geologists are right in regarding it as lying along the same volcanic line that extends southward through the Western Pacific from New Guinea, then it is probable that the vast post-Tertiary upheaval of the island groups (Solomon Islands, New Hebrides, &c.) which I have shown to have taken place along this line of volcanic activity in the Western Pacific, has been represented in New Zealand by elevation rather than depression. I believe that subsequent investigation will confirm my belief that the great island groups of the Western Pacific, with New Caledonia and New Zealand, have been always insular. This is, I think, the great lesson I learned in the Solomon Islands.

H. B. GUPPY.

LORD HARTINGTON ON TECHNICAL EDUCATION.

THE Marquis of Hartington was the chief guest at the anniversary banquet of the Institution of Mechanical Engineers held on Friday, May 4, at the Criterion Restaurant. Mr. Edward H. Carbutt, President of the Institution, occupied the chair. In responding to the toast of "Our Guest," proposed by the Chairman, Lord Hartington, after speaking of the part which the mechanical engineering profession of this country takes in the maintenance and the extension of our material and industrial supremacy in the world, referred to the vast importance of technical education. He had never professed to be an authority on the subject of technical education—he was no authority on that subject; all he could do in the position he held was to endeavour to arouse such interest as he could in that subject, to enlist in the minds of the ordinary public—the unscientific public of whom he formed a part—an interest in this question, and to listen to the advice and attend to the counsel which were given to the public by those who were authorities on the subject, and to whose advice he held it was most important that attention should be paid. He had been greatly struck by the fact that in every country in Europe which competed with us in industrial or commercial pursuits greater attention had recently been paid to giving a practical direction to the national education than had hitherto been considered necessary in England. We had, like other countries—perhaps somewhat in arrear of them—established a national and tolerably complete instruction; but they, earlier than we, had embraced the idea of making that national instruction not only a literary instruction, but a technical and commercial education. But he could not help thinking that in that respect they had gained some considerable advantages over ourselves. He did not think there was any occasion for us to take a desponding or a pessimistic view of the situation. He had great confidence in the energy, the skill, and the intelligence of our people. But he believed there were facts which it would be madness on our part to ignore. If a new process, a new invention, were discovered in any other country—if a new process of manufacture were discovered greatly superior to that which was in existence among ourselves—we should at once admit that it was necessary for us either to improve that invention or else to resign ourselves to being defeated in the competition for the production of that article. But if it were true, as he believed it was, that the system of national education in other countries was being devoted to purposes which made the manual labour of the working population more intelligent, more skilled, and therefore more valuable, that was a fact which was just as important and which had consequences of exactly the same character as if foreign nations were to discover an invention which was not available for our own use. These facts had been investigated by a Royal Commission, and by a great number of private individuals for their own purposes; and there was no sort of doubt that foreign countries had not only attempted to give, but had to a very considerable extent succeeded in giving, a more practical turn to the education of their people in all branches of industry and commerce where science and art could be usefully and successfully applied. If it were the fact that we had fallen behind in this branch of the instruction of our people, it appeared to him that it would be worse than idle, it would be criminal, on our part if we were for a moment to ignore the consequences of those facts, and the consequences which might result not only to our temporary commercial and manufacturing position in the world, but to the future industrial position of England. He was sure there were none to whose advice great employers and leaders of industry in this country would more cheerfully and more willing listen, none who exercised a greater influence over the public mind of this country, than those whom he had the honour of addressing; and it was a great satisfaction to him to be assured by the words that had fallen from their Chairman that they were giving their earnest and anxious attention to the subject of technical education.

NOTES.

A Royal Commission has been appointed to inquire "whether any and what kind of new University or powers is or are required for the advancement of higher education in London." The Commissioners are Lord Selborne, Chairman; Sir James Hannen, Sir William Thomson, Dr. J. T. Ball, Mr. G. C. Brodrick, the Rev. J. E. C. Welldon, and Prof. Stokes, P.R.S. Mr. J. L. Goddard is appointed Secretary to the Commission.

Much trouble was taken to secure the success of the annual *conversazione* of the Royal Society held last night. We shall give some account of it next week.

The Emperor Frederick has marked the opening of his reign by conferring personal honours on some eminent Germans. Dr. Werner Siemens, the electrician, is one of those who have been ennobled or dignified with the prefix "Von."

The Donders Memorial Fund, to which we called attention some time ago, now amounts to about £2000, of which £250 has been subscribed in England. Prof. Donders' seventieth birthday falls on Sunday, the 27th inst.; but it has been decided that the celebration in his honour shall take place on the following day. The subscription list, so far as this country is concerned, will be closed on the 14th inst.

At the general monthly meeting of the Royal Institution, on Monday last, Dr. Tyndall was elected Honorary Professor, and Lord Rayleigh Professor, of Natural Philosophy.

A preliminary meeting, called by invitation of the Council of the Yorkshire Philosophical Society, to consider the desirability of forming a Museum Association, was held in York on May 3. Among the Museums represented at the meeting were those of Liverpool, Manchester, York, Sheffield, Nottingham, Bolton, Bradford, Sunderland, and Warrington. It was unanimously decided that a Museum Association should be formed, and that it should consist of curators or those engaged in the active work of Museums, and also of representatives of the Committees or Councils of Management of Museums. The Association will consider (1) whether it may not be possible to secure a compendious index of the contents of all provincial museums and collections; (2) the most effectual methods of facilitating the interchange of specimens and books between various museums; (3) the best plans for arranging museums and classifying their contents; (4) the organization of some concerted action for the obtaining of such Government publications as are interesting or important from a scientific point of view.

Prof. Arthur Schuster, F.R.S., has been appointed to the Langworthy Professorship of Physics and Directorship of the Physical Laboratory at the Owens College, in succession to the late Prof. Balfour Stewart.

The Gaekwar of Baroda is reported to have decided to send a number of young men, carefully selected for the purpose, to study scientific and technical subjects in England, under the supervision of Mr. Gajjar, Professor of Biology in the Baroda College.

The Government of Ceylon have sanctioned the opening of a Forest School at Kandy.

We regret to have to record the death of Sir Charles Bright, the eminent electrician. He died last Thursday, at the age of fifty-six.

Dr. Sigismond Wróblewski, Professor of Experimental Physics at the Polish University of Cracow, died on April 16 last, in consequence of injuries received through the explosion of some petroleum lamps. Prof. Wróblewski lived for some time in London, and was afterwards a Professor at the University of Strasburg. He also worked in the laboratory of Prof. Debray in the École Normale, Paris. He accepted the appointment at Cracow in 1882. His researches on the liquefaction of gases are well known.

The sodium salt of a new sulphur acid, of the composition $H_2S_4O_8$, has been prepared by M. Villiers (*Bull. de Soc. Chim.*, 1888, 671). It was obtained by the action of sulphur dioxide upon a strong solution of sodium thiosulphate, and is tolerably stable, crystallizing in well-developed prisms. A quantity of crystalline sodium thiosulphate contained in a flask was treated with an amount of water insufficient for complete solution; the flask was immersed in iced water, and a current of sulphur dioxide passed, with constant agitation, until the solution was saturated and all or nearly all the thiosulphate had dissolved. If any of the latter crystals remained undissolved, a little more water was added, and the solution again saturated with the gas, repeating this treatment until all had passed into solution. After leaving the liquid thus obtained at the ordinary temperature for two or three days, it was found to be capable of taking up a further considerable volume of sulphur dioxide, the former quantity having evidently entered into chemical combination in some way or other. It was therefore again saturated, and left for another day or two, after which the solution was evaporated *in vacuo* over sulphuric acid. It was then found that a precipitate of sulphur was gradually deposited upon the base of the containing dish, while fine white prisms of brilliant lustre were formed at the surface. On analysis they were found to be anhydrous, and yielded numbers corresponding to the formula $Na_2S_4O_8$ or NaS_2O_4. They dissolved in water with formation of a neutral solution. On again evaporating this solution under the receiver of the air-pump, crystals of a hydrate, $Na_2S_4O_8 + 2H_2O$, separated out. From the remarkable similarity in properties between oxygen and sulphur, it is probable that this new acid by no means exhausts all the possible combinations, for it appears as if one is capable of replacing the other to any extent, forming compounds which may perhaps be considered as oxygen substitution derivatives of polysulphides. M. Villiers has not yet completed his investigation of the properties and constitution of the new acid, further details of which will be awaited with considerable interest.

ON April 2 a severe shock of earthquake was felt at Kalleli, in the Lysefjord. It occurred simultaneously with one at Gjæsdal, also on the west coast of Norway. In the former place three distinct shocks were felt, causing the windows to rattle, clocks to stop, &c. A loud subterranean rumbling was heard. On the other side of the narrow fjord no shock was felt, but a deep rumbling detonation was heard.

ON the morning of April 18 a severe shock of earthquake was felt at Vexiö, in the south of Sweden. It lasted fully two minutes, and was followed by subterranean detonations. This is the third earthquake observed in this district during the last six months.

THE Calcutta Correspondent of the *Times* telegraphs that India has been visited by a series of what he calls "phenomenal" storms, partaking very much of the character of the Dacca tornado. At Moradabad, 150 deaths are reported, caused chiefly by hailstones. Many of the houses were unroofed, trees were uprooted, and masses of frozen hail remained lying about long after the cessation of the storm. At Delhi there was an extraordinary hailstorm lasting about two minutes, which was virtually a shower of lumps of ice. One of the hailstones picked up in the hospital garden weighed 1½ lb.; another, secured near the Telegraph Office, was of the size of a melon, and turned the scale at 2 lbs. At another place the Government House suffered severely, 200 panes of glass being broken by hail. In Lower Bengal, at Rayebati, 2000 huts were destroyed, while twenty persons are reported to have been killed and 200 severely injured. Chudressur, close to Serampore, was almost completely wrecked. The storm lasted only three minutes, its course extending for a mile and a half, and its path being 300 yards wide. Its advent was preceded by a loud booming noise. Large boats were lifted out of the river, and in one case a small boat was blown up into a tree.

ACCORDING to an official report, the substance of which has been given by the Calcutta Correspondent of the *Times*, an immense amount of injury was done by the Dacca tornado. No fewer than 118 persons were killed, excluding those drowned, and 1200 wounded had to be treated. The amount of the damage to property is estimated at Rs.6,78,428. Three hundred and fifty-eight houses were completely destroyed, 121 boats were wrecked, and 148 brick-built houses were partially, and 9 were completely, destroyed. Shortly after the Dacca tornado, another visited part of the Murchagunje subdivision, and 66 deaths and 128 cases of injury are reported. All the houses struck were completely destroyed. The Dacca tornado travelled altogether 3¼ miles. Its rate of speed varied from 12 to 20 miles, and its greatest width was 20 yards. It was accompanied by a rumbling hissing sound, the clouds over it were illuminated, and liquid mud was deposited along its track, and was ingrained in the wounds of the injured.

WE are glad to be able to report, on the authority of Captain de Brito Capello, Director of the Lisbon Observatory, that the Government of Brazil has established a Meteorological Service there, by decree dated April 4 last. The Director is Senhor A. Pinheiro, who has visited this country on several occasions.

AT the meeting of the French Meteorological Society, on the 3rd of April, M. Vaussenat presented and analyzed a long series of photographs of clouds taken at the Observatory of the Pic-du-Midi, from 1880 to 1887, under all conditions of the atmosphere. He drew special attention to the importance of the systematic observation of clouds, at that mountain observatory, and stated that by the aid of such observations he had been able to issue local predictions of weather which had acquired great accuracy. M. Grad gave particulars respecting the present meteorological organization in Alsace and Lorraine. In 1870, the Meteorological Commission presided over by M. Hirn established a complete network of stations, but this service was interrupted by the war which broke out soon after. At present there are twenty stations in the two provinces. One of these, viz. Strasburg, possesses an unbroken series of observations since 1801. It has been decided to establish a service there for the issue of weather forecasts for the benefit of agriculture.

MR. T. WILSON, of the Smithsonian Institution, gives in the *American Naturalist* an interesting account of some recent discoveries made by Mr. Frank Cushing, who has not only been adopted by the tribe of Zuñis, but initiated into the order of their priesthood. While at Tempe, in Arizona, in the spring of 1887, Mr. Cushing heard of a large truncated mound in the desert 6 or 7 miles to the south-east. He visited it, and declared it to be of artificial formation. Workmen were brought from Tempe, and in a short time they came upon the ruins of an immense building. Mr. Cushing at once arrived at the conclusion that this building had been used as an Indian temple. He observed many things which corresponded in a remarkable degree with the Zuñi religion, and which he was able to recognize in consequence of the experience he had gained as a priest. Continuing his explorations, he found the remains of a city 3 miles long and at some places 1 mile wide. This city was somewhat irregularly laid out, consisting principally of large squares or blocks of houses surrounded by a high wall, apparently for protection. The state of the buildings clearly indicated that the city had been ruined by an earthquake. Many bodies crushed by fallen roofs and walls were found. Mr. Cushing also discovered a number of graves, believed to be the graves of priests. The symbols and decorations on the pottery found in these graves resemble the symbols and decorations on modern Zuñi pottery. About 10 or 15 miles from this ruined city, which Mr. Cushing calls Los Muertos, the City of the Dead, he has lately found the remains of another prehistoric town, in connection with which there are many traces of extensive works for irrigation.

THE Boston Society of Natural History proposes to establish a Zoological Garden in that city. The enterprise will be thoroughly educational. The chief object will be to show specimens of American animals, especially those of New England.

ACCORDING to a telegram from Sydney, the Conference upon the means of dealing with the rabbit-pest in Australia has resulted in the selection of an island where M. Pasteur's and other methods of extirpation will be thoroughly tried. The liability of other animals and birds to infection by the same means will also be tested.

DURING the month of July the following courses, for technical teachers and others, will be given in the new buildings of the City and Guilds of London Institute:—Elementary Principles of Machine-Designing, by Prof. W. C. Unwin, F.R.S.; Practical Lessons in Organic Chemistry, intended mainly for teachers of technological subjects, by Prof. Armstrong, F.R.S.; the Construction and Use of Electrical Measuring Instruments, by Prof.

Ayrton, F.R.S.; Experimental Mechanics, by Prof. Henrici F.R.S.; the Principles of Bread-making, by William Iago; Photography, by Capt. Abney, F.R.S.; Mathematical and Surveying Instruments, by Arthur Thomas Walmisley; Gas Manufacture, by Lewis T. Wright; the Application of Modern Geometry to the Cutting of Solids for Masonry and other Technical Arts, by Lawrence Harvey; and the Craft of the Carpenter, by John Slater.

THE additions to the Zoological Society's Gardens during the past week include two Long-eared Bats (*Plecotus auritus*), from Cornwall, presented by Mr. F. A. Allchin; a —— Roe (*Capreolus* —— ♀), from Corea, presented by Mr. F. Harston Eagles; two Burrowing Owls (*Speotyto cunicularia*), from Buenos Ayres, presented by Mr. J. Clark Hawkshaw; a Blue and Yellow Macaw (*Ara ararauna*), from Para, presented by Mrs. Yarrow; two Crested Ducks (*Anas cristatus*), from the Falkland Islands, presented by Mr. F. E. Cobb, C.M.Z.S.; an Asp Viper (*Vipera aspis*), from Italy, presented by Messrs. Paul and Co.; a Common Viper (*Vipera berus*), from Burnham Beeches, presented by Mr. F. M. Oldham; two Japanese Deer (*Cervus sika* ♂ ♂), from Japan; a Macaque Monkey (*Macacus cynomolgus* ♂), from India, a Vulpine Phalanger (*Phalangista vulpina* ♂), from Australia, two Burrowing Owls (*Speotyto cunicularia*), from Buenos Ayres, deposited; a Spotted Cavy (*Cœlogenys paca*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

NEW MINOR PLANETS.—Herr Palisa, at Vienna, discovered a new minor planet, No. 276, on April 17, and M. Charlois, at Nice, discovered a second, No. 277, on May 3, the sixty-fourth and third discoveries respectively of the two astronomers. No. 273 has been named Atropos.

COMET 1888 *a* (SAWERTHAL).—The following ephemeris (*Dun Echt Circular*, No. 155) is in continuation of that given in NATURE, vol. xxxvii. p. 520:—

For Greenwich Midnight.

1888.	R.A. h. m. s.	Decl. ° ′	Log Δ.	Log *r*.	Brightness.
May 10	23 45 45	31 39·8 N.	0·2242	0·1003	0·14
12	23 50 0	32 33·7			
14	23 54 9	33 25·8	0·2360	0·1198	0·12
16	23 58 12	34 16·1			
18	0 2 8	35 4·7	0·2470	0·1386	0·11
20	0 5 58	35 51·7			
22	0 9 42	36 37·2	0·2572	0·1566	0·09
24	0 13 20	37 21·2			
26	0 16 51	38 3·9	0·2666	0·1738	0·08
28	0 20 16	38 45·3			
30	0 23 35	39 25·6	0·2752	0·1904	0·07

The brightness at discovery is taken as unity.

CINCINNATI ZONE CATALOGUE.—No. 9 of the Publications of the Cincinnati Observatory contains a zone catalogue of 4050 stars observed during 1885, 1886, and the early part of 1887 with the 3-inch transit instrument of the Observatory, made by Buff and Berger. The region covered by the zones is from S. Decl. 18° 50′ to S. Decl. 22° 20′, most of the stars down to mag. 8·5 having been observed, besides a considerable number of fainter ones. A low power was employed, so as to give a field of 50′ in breadth, and as the zones were taken 15′ apart, each star was thus usually observed in three zones. The R.A.'s were deduced from transits, recorded on a chronograph, over a system of five vertical wires; the declinations, from bisections by a micrometer wire, two readings being taken for each star whenever practicable. The probable error of a single observation was found to be R.A. ± 0·123s., Decl. ± 1″·84, the observations being a little rougher than could have been desired, in consequence of the low magnifying power used. An important portion of the work has been the comparison of the resulting places with those for the same stars in earlier catalogues, and a considerable number of errata in Lalande's, Lamont's, and other catalogues have been detected. A list of seventy-five proper motions, nearly all of them new, is likewise added.

PUBLICATIONS OF LICK OBSERVATORY.—The first volume of the Publications of the Lick Observatory has been received. It is chiefly occupied with the details of the progress of the institution from the date of Mr. Lick's first deed of trust, 1874, and with the description of the smaller instruments, the great refractor being reserved for a future volume. Meteorological observations taken on Mount Hamilton from 1880 to 1885, and reduction tables for the Observatory occupy a large part of the volume. Amongst the most interesting reports are those of Prof. Newcomb, on the glass for the great objective; of Mr. Burnham, on Mount Hamilton as an observing station; and of Prof. Todd, on the transit of Venus, 1882. A report on the structure of the mountain is also given by Profs. Irving and Jackson.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 MAY 13–19.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 13

Sun rises, 4h. 12m.; souths, 11h. 56m. 9·7s.; sets, 19h. 40m.: right asc. on meridian, 3h. 22·8m.; decl. 18° 34′ N. Sidereal Time at Sunset, 11h. 8m.

Moon (at First Quarter May 18, 23h.) rises, 5h. 58m.; souths, 13h. 54m.; sets, 21h. 57m.: right asc. on meridian, 5h. 21·2m.; decl. 19° 46′ N.

THE PYGMY RACES OF MEN.[1]

I.

IT is well known that there existed among the nations of antiquity a wide-spread belief in the existence of a race or races of human beings of exceedingly diminutive stature, who dwelt in some of the remote and unexplored regions of the earth. These were called *Pygmies*, a word said to be derived from πυγμή, which means a fist, and also a measure of length, the distance from the elbow to the knuckles of an ordinary-sized man, or rather more than 13 inches.

In the opening of the third book of the *Iliad*, the Trojan hosts are described as coming on with noise and shouting, "like the cranes which flee from the coming of winter and sudden rain, and fly with clamour towards the streams of ocean, bearing slaughter and fate to the Pygmy men, and in early morn offer cruel battle," or, as Pope has it—

"So when inclement winters vex the plain,
With piercing frosts, or thick descending rain,
To warmer seas the cranes embodied fly,
With noise and order through the midway sky,
To Pygmy nations wounds and death they bring,
And all the war descends upon the wing."

The combats between the pygmies and the cranes are often alluded to by late classical writers, and are not unfrequently depicted upon Greek vases. In one of these in the Hope collection at Deepdene, in which the figures are represented with great spirit, the pygmies are dwarfish-looking men with large heads, negro features, and close woolly or frizzly hair. They are armed with lances. Notices of a less poetical and apparently more scientific character of the occurrence of very small races of human beings are met with in Aristotle, Herodotus, Ctesias, Pliny, Pomponius Melo, and others. Aristotle places his pygmies in Africa, near the sources of the Nile, while Ctesias describes a race of dwarfs in the interior of India. The account in Herodotus is so circumstantial, and has such an air of truthfulness about it, especially in connection with recent discoveries, that it is worth quoting in full.[2]

"I did hear, indeed, what I will now relate, from certain natives of Cyrênê. Once upon a time, they said, they were on a visit to the oracular shrine of Ammon, when it chanced that, in the course of conversation with Etearchus, the Ammonian king, the talk fell upon the Nile, how that its sources were unknown to all men. Etearchus upon this mentioned that some Nasamonians had once come to his Court, and when asked if they could give any information concerning the uninhabited parts of Libya, had told the following tale. The Nasamonians are a Libyan race who occupy the Syrtes, and a tract of no great size towards the east. They said there had grown up among them some wild young men, the sons of certain chiefs, who, when they came to man's estate, indulged in all manner of extravagancies, and among other things drew lots for five of their number to go and explore the desert parts of Libya, and try if they could not penetrate further than any had done previously. The young men therefore dispatched on this errand by their comrades with a plentiful supply of water and provisions, travelled at first through the inhabited region, passing which they came to the wild beast tract, whence they finally entered upon the desert, which they proceeded to cross in a direction from east to west. After journeying for many days over a wide extent of sand, they came at last to a plain where they observed trees growing: approaching them, and seeing fruit on them, they proceeded to gather it. While they were thus engaged, there came upon them some dwarfish men, under the middle height, who seized them and carried them off. The Nasamonians could not understand a word of their language, nor had they any acquaintance with the language of the Nasamonians. They were led across extensive marshes, and finally came to a town, where all the men were of the height of their conductors, and black-complexioned. A great river flowed by the town, running from west to east, and containing crocodiles."

It is satisfactory to know that the narrative concludes by saying that these pioneers of African exploration, forerunners of Bruce and Park, of Barth, Livingstone, Speke, Grant, Schweinfurth, Stanley, and the rest, "got safe back to their country."

Extension of knowledge of the natural products of the earth, and a more critical spirit on the part of authors, led to attempts of explanation of this belief, and the discovery of races of monkeys—of the doings of which, it must be said, more or less fabulous stories were often reported by travellers—generally sufficed the commentators and naturalists of the last century to explain the origin of the stories of the pygmies. To this view the great authority of Buffon was extended.

Still more recently-acquired information as to the actual condition of the human population of the globe has, however, led to a revision of the ideas upon the subject, and to more careful and critical researches into the ancient documents. M. de Quatrefages, the eminent and veteran Professor of Anthropology at the Muséum d'Histoire Naturelle of Paris, has especially carefully examined and collated all the evidence bearing upon the question, and devoted much ingenuity of argument to prove that the two localities in which the ancient authors appear to place their pygmies, the interior of Africa near the sources of the Nile, and the southernmost parts of Asia, and the characters they assign to them, indicate an actual knowledge of the existence of the two groups of small people which still inhabit these regions, the history of which will form the subject of this lecture. The evidence which has convinced M. de Quatrefages, and which, I have no doubt, will suffice for those who take pleasure in discovering an underlying truth in all such legends and myths, or in the more grateful task of rehabilitating the veracity of the fathers of literature and history, will be found collected in a very readable form in a little book published last year in the "Bibliothèque scientifique contemporaine," called "Les Pygmées," to which I refer my readers for fuller information upon the subject of this discourse, and especially for numerous references to the literature of the subject, which, as the book is accessible to all who wish to pursue it further, I need not give here.

It is still, however, to my mind, an open question whether these old stories may not be classed with innumerable others, the offspring of the fertile invention of the human brain, the potency of which as an origin of myths has, I think, sometimes been too much underrated. I shall therefore now take leave of them, and confine myself to giving you, as far as the brief space of time at my disposal admits, an account of our actual knowledge of the smallest races of men either existing or, as far as we know, ever having existed on earth, and which may therefore, taking the word in its current though not literal sense, be called the "pygmies" of the species.

Among the various characters by which the different races of men are distinguished from one another, *size* is undoubtedly one of considerable importance. Not but what in each race there is much individual variation, some persons being taller, and some shorter; yet these variations are, especially in the purer or less mixed races, restricted within certain limits, and there is a general average, both for men and women, which can be ascertained when a sufficient number of accurate measurements have been recorded. That the prevailing size of a race is a really deeply-seated, inherited characteristic, and depends but little on outward conditions, as abundance of food, climate, &c., is proved by well-known facts. The tallest and the shortest races in Europe are respectively the Norwegians and the Lapps, living in almost the same region. In Africa, also, the diminutive Bushmen and the tallest race of the country, the Kaffirs, are close neighbours. The natives of the Andaman Islands and those of many islands of the equatorial region of the Pacific, in which the conditions are similar, or if anything more favourable to the former, are at opposite ends of the scale of height. Those not accustomed to the difficulties both of making and recording such measurements will scarcely be prepared, however, to learn how meagre, unsatisfactory and unreliable our knowledge of the stature of most of the races of mankind is at present, although unquestionably it has been considerably increased within recent years. We must, however, make use of such material as we possess, and trust to the future correction of errors when better opportunities occur.

It is convenient to divide men, according to their height, into three groups—tall, medium, and short; in Topinard's system, the first being those the average height (of the men) of which is above 1·700 metres (5 feet 7 inches), the latter those below 1·500 metres (4 feet 11 inches), and the middle division those between the two. In the last division are included certain of the Mongolian or yellow races of Asia, as the Samoyedes, the Ostiaks, the Japanese, the Siamese, and the Annamites; also the Veddahs of Ceylon and certain of the wild hill-tribes of Southern India. These all range between 1·525 and 1·600 metres—say between 5 feet and 5 feet 3 inches.

[1] A Lecture delivered at the Royal Institution on Friday evening, April 13, 1888, by Prof. Flower, C.B., LL.D., F.R.S., Director of the Natural History Departments of the British Museum.

[2] Herodotus, Book II. 32, Rawlinson's translation, p. 47.

It is of none of these people of whom I am going to speak to-day. My pygmies are all on a still smaller scale, the average height of the men being in all cases below 5 feet, in some cases, as we shall see, considerably below.

Besides their diminutive size, I may note at the outset that they all have in a strongly-marked degree the character of the hair distinguished as frizzly—*i.e.* growing in very fine, close curls, and flattened or elliptical in section, and therefore, whatever other structural differences they present, they all belong to the same primary branch of the human species as the African Negro and the Melanesian of the Western Pacific.

I will first direct your attention to a group of islands in the Indian Ocean—the Andamans—where we shall find a race in many respects of the greatest possible interest to the anthropologist.

These islands are situated in the Bay of Bengal, between the 10th and 14th parallels of north latitude, and near the meridian 93° east of Greenwich, and consist of the Great and Little Andamans. The former is about 140 miles long, and has a breadth nowhere exceeding 20 miles. It is divided by narrow channels into three, called respectively North, Middle, and South Andaman, and there are also various smaller islands belonging to the group. Little Andaman is a detached island lying about 28 miles to the south of the main group, about 27 miles in length and 10 to 18 in breadth.

Although these islands have been inhabited for a very great length of time by people whose state of culture and customs have undergone little or no change, as proved by the examination of the contents of the old kitchen-middens, or refuse heaps, found in many places in them, and although they lie so near the track of civilization and commerce, the islands and their inhabitants were practically unknown to the world until so recently as the year 1858. It is true that their existence is mentioned by Arabic writers of the ninth century, and again by Marco Polo, and that in 1788 an attempt was made to establish a penal colony upon them by the East India Company, which was abandoned a few years after; but the bad reputation the inhabitants had acquired for ferocious and inhospitable treatment of strangers brought by accident to their shores caused them to be carefully avoided, and no permanent settlement or relations of anything like a friendly character, or likely to afford any useful information as to the character of the islands or the inhabitants, were established. It is fair to mention that this hostility to foreigners, which for long was one of the chief characteristics by which the Andamanese were known to the outer world, found much justification in the cruel experiences they suffered from the malpractices, especially kidnapping for slavery, of the Chinese and Malay traders who visited the islands in search of *bêche de mer* and edible birds'-nests. It is also to this characteristic that the inhabitants owe so much of their interest to us from a scientific point of view, for we have here the rare case of a population, confined to a very limited space, and isolated for hundreds, perhaps thousands, of years from all contact with external influence, their physical characters unmixed by crossing, and their culture, their beliefs, their language entirely their own.

In 1857, when the Sepoy mutiny called the attention of the Indian Government to the necessity of a habitation for their numerous convict prisoners, the Andaman Islands were again thought of for the purpose. A Commission, consisting of Dr. F. J. Mouat, Dr. G. Playfair, and Lieut. J. A. Heathcote was sent to the islands to report upon their capabilities for such a purpose; and, acting upon its recommendations, early in the following year the islands were taken possession of in the name of the East India Company by Captain (now General) H. Man, and the British flag hoisted at Port Blair, near the southern end of Great Andaman, which thenceforth became the nucleus of the settlement of invaders, now numbering about 15,000 persons, of whom more than three-fourths are convict prisoners, the rest soldiers, police, and the usual accompaniments of a military station.

The effect of this inroad upon the unsophisticated native population, who, though spread over the whole area of the islands, were far less numerous, may easily be imagined. It is simply deterioration of character, moral and physical decay, and finally extinction. The newly-introduced habits of life, vices, and diseases, are spreading at a fearful rate, and with deadly effect. In this sad history there are, however, two redeeming features which distinguish our occupation of the Andamans from that of Tasmania, where a similar tragedy was played out during the present century. In the first place, the British Governors and residents appear from the first to have used every effort to obtain for the natives the most careful and considerate treatment, and to alleviate as much as possible the evils which they have unintentionally been the means of inflicting on them. Secondly, most careful records have been preserved of the physical characters, the social customs, the arts, manufactures, traditions, and language of the people while still in their primitive condition. For this most important work, a work which, if not done, would have left a blank in the history of the world which could never have been replaced, we are indebted almost entirely to the scientific enthusiasm of one individual, Mr. Edward Horace Man, who most fortunately happened to be in a position (as Assistant Superintendent of the Islands, and specially in charge of the natives) which enabled him to obtain the required information with facilities which probably no one else could have had, and whose observations "On the Aboriginal Inhabitants of the Andaman Islands," published by the Anthropological Institute of Great Britain and Ireland, are most valuable, not only for the information they contain, but as correcting the numerous erroneous and misleading statements circulated regarding these people by previous and less well informed or less critical authors.

The Arab writer of the ninth century previously alluded to states that "their complexion is frightful, their hair frizzled, their countenance and eyes frightful, their feet very large, and almost a cubit in length, and they go quite naked," while Marco Polo (about 1285) says that "the people are no better than wild beasts, and I assure you all the men of this island of Angamanain have heads like dogs, and teeth and eyes likewise; in fact, in the face they are just like big mastiff dogs." These specimens of mediæval anthropology are almost rivalled by the descriptions of the customs and moral character of the same people published as recently as 1862, based chiefly on information obtained from one of the runaway sepoy convicts, and which represent them as among the lowest and most degraded of human beings.

The natives of the Andamans are divided into nine distinct tribes, each inhabiting its own district. Eight of these live upon the Great Andaman Islands, and one upon the hitherto almost unexplored Little Andaman. Although each of these tribes possesses a distinct dialect, these are all traceable to the same source, and are all in the same stage of development. The observations that have been made hitherto relate mostly to the tribe inhabiting the south island, but it does not appear that there is any great variation either in physical characters or manners, customs, and culture among them.

With regard to the important character of size, we have more abundant and more accurate information than of most other races. Mr. Man gives the measurements of forty-eight men and forty-one women, making the average of the former 4 feet $10\frac{3}{4}$ inches, that of the latter 4 feet $7\frac{1}{4}$ inches, a difference therefore of $3\frac{1}{2}$ inches between the sexes. The tallest man was 5 feet $4\frac{1}{4}$ inches; the shortest 4 feet 6 inches. The tallest woman 4 feet $11\frac{1}{2}$ inches; the shortest 4 feet 4 inches. Measurements made upon the living subject are always liable to errors, but it is possible that in so large a series these will compensate each other, and that therefore the averages may be relied upon. My own observations, based upon the measurements of the bones alone of as many as twenty-nine skeletons, give smaller averages, viz. 4 feet $8\frac{1}{2}$ inches for the men, and 4 feet $6\frac{1}{2}$ inches for the women; but these, it must be recollected, are calculated from the length of the femur, upon a ratio which, though usually correct for Europeans, may not hold good in the case of other races.[1] The hair is fine, and very closely curled; woolly, as it is generally called, or, rather, frizzly, and elliptical in section, as in the Negroes. The colour of the skin is very dark, although not absolutely black. The head is of roundish (brachycephalic) form, the cephalic index of the skull being about 82. The other cranial characters are fully described in the papers just referred to. The teeth are large, but the jaws are only slightly prognathous. The features possess little of the Negro type; at all events, little of the most marked and coarser peculiarities of that type. The projecting jaws, the prominent thick lips, the broad and flattened nose of the genuine Negro are so softened down in the Andamanese as scarcely to be recognized, and yet in

[1] See "On the Osteology and Affinities of the Natives of the Andaman Islands" (Journal Anthropological Institute, vol. ix. p. 108, 1879); and "Additional Observations on the Osteology of the Natives of the Andaman Islands" (*ibid.*, vol. xiv. p. 115, 1884).

the relative proportions of the limb-bones, especially in the shortness of the humerus compared with the fore-arm, and in the form of the pelvis, Negro affinities are most strongly indicated.

In speaking of the culture of the Andamanese, of course I only refer to their condition before the introduction of European civilization into the islands. They live in small villages or encampments, in dwellings of simple and rude construction, built only of branches and leaves of trees. They are entirely ignorant of agriculture, and keep no poultry or domestic animals. They make rude pots of clay, sun-dried, or partially baked in the fire, but these are hand-made, as they are ignorant of the use of the potter's wheel. Their clothing is of the scantiest description, and what little they have chiefly serves for decorative or ornamental purposes, and not for keeping the body warm. They make no use of the skins of animals. They have fairly well-made dug-out canoes and outriggers, but only fit for navigating the numerous creeks and straits between the islands, and not for voyages in the open sea. They are expert swimmers and divers. Though constantly using fire, they are quite ignorant of the art of producing it, and have to expend much care and labour in keeping up a constant supply of burning or smouldering wood. They are ignorant of all metals; but for domestic purposes make great use of shells, especially a species of *Cyrene* found abundantly on the shores of the islands, also quartz chips and flakes, and bamboo knives. They have stone anvils and hammers, and they make good string from vegetable fibres, as well as baskets, fishing-nets, sleeping-mats, &c. Their principal weapons are the bow and arrow, in the use of which they are particularly skilful. They have harpoons for killing turtle and fish, but no kind of shield or breastplate for defence when fighting. The natural fertility of the island supplies them with abundance and a great variety of food all the year round, the purveying of which affords occupation and amusement for the greater part of the male population. This consists of pigs (*Sus andamanensis*), which are numerous on the islands, paradoxurus, dugong, and occasionally porpoise, iguanas, turtles, turtles' eggs, many kinds of fish, prawns, mollusks, larvæ of large wood-boring and burrowing beetles, honey, and numerous roots (as yams), fruits, and seeds. The food is invariably cooked before eating, and generally taken when extremely hot. They were ignorant of all stimulants or intoxicating drinks—in fact, water was their only beverage; and tobacco, or any substitute for it, was quite unknown till introduced by Europeans.

(*To be continued.*)

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE Institution of Mechanical Engineers held its annual meeting at the house of the Institution of Civil Engineers in Great George Street, Westminster, on the 3rd and 4th inst., under the presidency of Mr. E. H. Carbutt.

The papers brought forward for reading and discussion were: the Third Report of the Research Committee of the Institution on Friction; "Description of the Emery Testing Machine," by Mr. Henry R. Towne, of Stamford, Connecticut, U.S.A.; and "Supplementary Paper on the Use of Petroleum Refuse as Fuel in Locomotive Engines," by Mr. Thomas Urquhart, Locomotive Superintendent, Grazi and Tsaritsin Railway, South-East Russia; the third of which was deferred till the next meeting of the Institute.

The third report of the Friction Committee is on experiments on the friction of a collar-bearing. The general conclusions of the Committee are that this kind of bearing is inferior to a cylindrical journal in weight-carrying power. The coefficient of friction is also much higher than for a cylindrical bearing, and the friction follows the law of the friction of solids more nearly than that of liquids, due doubtless to the less perfect lubrication applicable to this form of bearing compared with a cylindrical one. The coefficient of friction appears to be independent of the speed, but to diminish somewhat as the load is increased, and may be stated approximately at $\frac{1}{20}$ at 15 lbs. per square inch, diminishing to $\frac{1}{30}$ at 75 lbs. per square inch.

In the broad principles of construction on which the Emery system of testing and weighing machinery rests are included two radically new and highly important elements—namely, an arrangement of hydraulic chambers and diaphragms capable of receiving without injury pressures and shocks of great intensity, and of transmitting them simultaneously, without loss from friction, to a convenient point for the purpose of measuring and recording them, and capable also of reducing them to such lower term of degree as may be desirable; and a means for flexibly uniting a vibrating scale-beam either to a fixed abutment or to another beam of the same system, in such a manner as absolutely to eliminate friction, and to preserve indefinitely the fulcrum intervals or distances precisely as first adjusted, and to resist and transmit all the pressures and shocks to which the fulcrums are subjected, without in the slightest degree impairing their sensitiveness or durability.

The hydraulic construction is such that through it the strain on the specimen is transmitted without loss to a hydraulic chamber containing a thin film of liquid, which is again transmitted through a small copper tube, without loss from friction or otherwise, to a much smaller chamber containing a similar thin film of liquid. The acting area of the liquid in the smaller chamber is less than that in the larger in the proportion in which the load on the specimen is desired to be reduced before it is received upon the beams in the scale-case where it is measured. In the scale-case containing the weighing mechanism, the pressure transmitted from the smaller chamber is received at one end of a system of levers, and measured by means of devices which are shown in detail in the figures which accompanied the paper.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Among the courses of lectures announced for this Term we may notice the following:—

In Physics, Prof. Clifton is lecturing on Optical Properties of Crystals, and Mr. Selby on Absolute Electrical Units, at the Clarendon Laboratory. At Christ Church, Mr. Baynes lectures on Thermo-dynamics, and on the Transfer of Energy in an Electro-magnetic Field.

The University has made a grant to Mr. Smith, in aid of the Millard Engineering Laboratory, and practical work on the physical basis of engineering is regularly carried on there.

In Chemistry, besides the usual courses, Mr. Veley is lecturing on Thermo-chemistry, and Mr. Marsh on Recent Organic Research.

The work of the Geological Chair is at present being done by Mr. W. W. Watts (M.A. Camb.), who is lecturing for a term in order that Prof. Green may complete his session at the Yorkshire College.

Owing to Prof. Moseley's continued illness, Dr. Hickson is still acting as Deputy Linacre Professor, and is lecturing on the Morphology of the Chordata. Mr. Bourne, who is to assume his post as Superintendent of the Plymouth Marine Station in a month, is lecturing on Embryology, and Prof. Westwood on the Winged Arthropoda.

Dr. Burdon-Sanderson lectures this Term on Nutrition, and Dr. Gilbert on the Rotation of Crops.

In the absence of any Professor of Botany, Mr. J. B. Farmer is conducting the necessary elementary courses.

CAMBRIDGE.—Prof. Adams is appointed one of the four representatives of Cambridge at the 800th anniversary of the foundation of the University of Bologna, in June next.

An additional class-room for students of Mineralogy is to be formed.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 19.—"The Radio-Micrometer." By C. V. Boys.

The author gave the result of a mathematical investigation made with a view to arrive at the best possible construction of the radio-micrometer already described by him. At the conclusion of the meeting he showed in action an instrument which he had made, having the best proportions, which was both simpler in construction and far more sensitive than the one he exhibited on a previous occasion.

"On the Compounds of Ammonia with Selenium Dioxide." By Sir Charles A. Cameron, M.D., F.R.C.S.I., and John Macallan, F.I.C.

On passing dry ammonia into a solution of selenium dioxide in absolute alcohol, a compound is formed to which the authors have assigned the name ammonium selenosamate, and the formula NH_4,SeO_2NH_2. It is the ammonium salt of a new acid; namely, H,SeO_2NH_2. It is unstable, continuously evolving ammonia, and ultimately becoming a stable acid salt, $NH_4,H,(SeO_2NH_2)_2$. The neutral salt forms hexagonal prisms and pyramids, and the acid forms prismatic crystals. The neutral salt dissolves in 116 parts of alcoholic ammonia, but is decomposed by absolute alcohol or by water.

April 26.—"On the Modifications of the First and Second Visceral Arches, with especial Reference to the Homologies of the Auditory Ossicles." By Hans Gadow, Ph.D., M.A., Strickland Curator and Lecturer on Comparative Anatomy in the University of Cambridge. Communicated by Prof. M. Foster, Sec. R.S.

The phylogenetic development of the first two visceral arches shows us some most interesting changes of function, which we can follow upwards from the lower Selachians to the highest Mammals.

Originally entirely devoted to respiration as gill-bearing structures, the whole hyoidean arch becomes soon a factor in the alimentary system. Its proximal half forms the hinge of the masticatory apparatus, its distal half remains henceforth connected with the process of deglutition. Then this suspensorial arrangement is superseded by a new modification; the hyomandibula is set free and would disappear (it does nearly do so in Dipnoi and certain Urodela), unless it were made use of for a new function; with its having entered the service of the conduction of sound, it has entered upon a new departure, and it is saved from degeneration. The whole system of the one to four elements of the middle ear, which all have the same function as conductors of sound, is to be looked upon as *one* organ of *one* common origin,—namely, as a modification of the hyomandibula, the primitive proximal paramere of the second visceral arch.

Successive Modifications of the Mandibular and Hyoidean Visceral Arches.

I. Primitive condition (Notidanidæ). The palato quadrate bar alone carries the mandible. The second arch is indifferent. Hyomandibula and quadrate (the palatine part is an outgrowth) are both attached to the cranium.

II. The hyomandibula gains a fibro cartilaginous connection with the mandible, the masticatory apparatus becomes amphistylic and occasionally hyostylic (Rajidæ, most Selachians).

The hyoid gains a cranial attachment (many Rajidæ).

III. The quadrate or autostylic suspensorium becomes preponderant; the hyomandibula is, as in Teleosteans, divided into a proximal and into a distal (symplectic) element. The proximal part is received into a fenestra of the otic capsule, and is converted into a stapes, whilst the distal half either remains (*Proteus*, *Siren*, *Menopoma*) or is lost (other Urodela). The whole hyomandibula would have been lost owing to its excalation from suspensorial functions, unless it had entered the auditory service.

IV. The autostylic arrangement prevails. The whole hyomandibula remains, gains an attachment on the "tympanum" and differentiates itself into several conjointed pieces, notably stapes or columella proper, and extra-columella or malleus.

The extra-columella gains connection with the parotic cartilage; this connection frequently remains, but in *Anura* alone it conatins a special element of probably parotic origin.

The quadrate forms an important part of the tympanic frame.

IV*a*. Collateral departure of the *Anura*. The connection between the tympanal part of the hyomandibula with the mandible is lost.

V. The quadrate still forms the principal suspensorial part of the mandible. The extra-columella, or malleus, retains for a long time its previously acquired connection with Meckel's cartilage (*Amniota*).

V*a*. The top end of the hyoid is attached to the cranium (*Geckos*, *Mammalia*), and is occasionally fused with the extra-columella (*Hatteria*).

V*b*. Or, the proximal portion of the hyoid is removed from the skull and remains otherwise well developed (*most Lizards*); or its proximal portion becomes reduced and lost (*Chelonia*, *Crocodilia*, *Ophidia*, *Aves*).

V*c*. The extra-columella gains an attachment to the quadrate, squamosal, or pterygoid, whilst its connections with the mandible (*Ophidia*, *Chamæleon*), and the tympanum, are lost.

VI. The quadrate gradually loses its articulation with the mandible; the latter gains a new outer articulation with the squamosal; the quadrate acts almost entirely as a tympanic frame. Incus and malleus fuse sometimes with each other, and lean on to the parotic region. The masticatory joint is doubly concave-convex (*Monotremata*).

VII. The quadrate is converted into the principal part of the tympanic frame, viz. annulus tympanicus. The mandible has lost its articulation with the quadrate, and the masticatory joint is a single concave-convex one, the convexity belonging to the mandible (*Monodelphia*).

EDINBURGH.

Royal Society, April 2.—Rev. Prof. Flint, Vice-President, in the chair.—Prof. Crum Brown communicated a paper by Dr. Prafulla Chandra Rây on the conjugated sulphates of the copper-magnesium group.—Dr. John Murray read a paper by Mr. A. Dickie on the chemical analysis of water from the Clyde area.—Sir W. Turner read a paper by Prof. His on the principles of animal morphology.—Prof. Tait communicated two mathematical notes.

April 16.—Prof. Chrystal, Vice-President, in the chair.—Dr. Buchan gave an analysis of the *Challenger* meteorological observations, pointing out various important meteorological conditions the existence of which had been revealed by the work of the *Challenger* Expedition.—Dr. John Murray read a description of the rocks of the Island of Malta, comparing them with deep-sea deposits.—Prof. Chrystal described an electrical method of reversing deep-sea thermometers.—Dr. Thomas Muir read a paper on a class of alternants expressible in terms of simple alternants.—Prof. Tait communicated a quaternion note.

PARIS.

Academy of Sciences, April 30.—M. Janssen, President, in the chair.—On the consequences of the equality assumed to exist between the true and the mean value of a polynome, by M. J. Bertrand. The author shows by a rigorous demonstration that the rule is not justified which gives *a posteriori* the precise value of a system of observations, although this rule is frequently applied with complete confidence in its accuracy.—On the theory of the figure of the earth, by M. Maurice Lévy. The point here mainly discussed is the difficulty of establishing a satisfactory agreement between the theory of fluidity and that of precession in connection with Clairaut's differential equation and the subsequent researches of Lipschitz inserted in vol. lxii. of the *Journal de Crelle*.—Remarks in connection with Père Dechevrens' recent note on the ascending movement of the air in cyclones, by M. H. Faye. In order to solve by direct observation the question of the ascending or descending movement of the atmosphere in cyclones, Père Dechevrens has devised a special anemometer for his observatory of Zi-Ka-Wei in China. But he suggests that more trustworthy results might perhaps be obtained by fitting up a similar apparatus at a greater elevation from the ground; for instance, on the top of Eiffel's Tower, 300 metres high, now being erected in Paris. M. Faye accepts this suggestion, confident that, if carried out, it cannot fail to confirm his own views on the movement of the atmospheric currents in cyclones.—An elementary proof of Dirichlet's theorem on arithmetical progressions in cases where the ratio is 8 or 12, by Prof. Sylvester. In this demonstration the author starts from the following principle: To show that the number of prime numbers of a given form is infinite, let an infinite progression be constructed of integers relatively prime to each other, and each containing a prime number at least of the given form.—Distribution in latitude of the solar phenomena recorded during the year 1887, by M. P. Tacchini. A table is given of the spots, eruptions, faculæ, protuberances, as observed in each zone of 10° in the two solar hemispheres. The hydrogenic protuberances occur in all the zones, whereas the other phenomena were almost entirely restricted to the central region between 0° and ± 40°, as in the previous year. The spots, faculæ, and metallic eruptions present an agreement in the respective zones of maximum frequency between 0° and ± 20°; a maximum for each of the three orders of phenomena corresponds to the zone 0°–10° exactly as in 1886. The spots were confined to the equatorial zone (+30°–20°); the eruptions and the faculæ occurred at much higher latitudes, in fact as far as +50° and −60°. Hence there are zones with faculæ and eruptions, but without spots, while on a great part of the solar surface hydrogenic protuberances are observed in the total absence of spots.—In a second communication, M. Tacchini gives a summary of the solar observations made at Rome during the first quarter of the year

1888. From this summary it appears that the phenomena of spots and faculæ still continue to decrease, while the protuberances have increased. This confirms the remark already made that there is no close relation between these two orders of phenomena.—Determination of the heats of combustion of the isomerous acids corresponding to the formulas $C_4H_4O_4$ and $C_5H_6O_4$, by M. W. Louguinine. The constituent formulas of the fumaric and pyromalic, as well as of the mesaconic, citraconic, and itaconic acids have been the subject of frequent discussions amongst chemists. In order to throw some light on these obscure questions, the author here determines the heats of combustion of the acids in question. He concludes generally that fumaric differs greatly from pyromalic acid, the former being the lower homologue of one of the three acids with formula $C_5H_6O_4$. The formulas corresponding to these three acids are evidently closely related, the difference here being of quite another order from that which exists between the formulas corresponding to the fumaric and pyromalic acids.—On the slow combustion of certain organic substances, by M. Th. Schlœsing. The author's experiments with tobacco seem to show that the combustion arising in heaps of foliage, hay, and the like is in the first instance due to the action of micro-organisms, but with the increase of temperature it gradually assumes a purely chemical character. The influence of living organisms appears to cease between 40° and 50° C., after which the chemical action rapidly increases.

BERLIN.

Meteorological Society, April 10.—Dr. Vettin, President, in the chair.—Dr. Zenker communicated the second part of his research on the distribution of heat over the earth's surface. In the first part, of which he had spoken at the last meeting of the Society, he had shown that the distribution of heat depends not only upon the radiation from the sun and absorption by the atmosphere, but additionally upon the nature of the earth's surface, whether it is land or water. In previous researches on the distribution of heat, the mean values were determined from and based upon empirical observations; Dr. Zenker, on the other hand, has calculated the distribution of heat over the surface of the sea with the help of Hann's isothermal charts, starting with the temperature of a point on its surface which was quite uninfluenced by the neighbouring continents, and was consequently equally unaffected by any warm or cold currents. Using this factor, and the formulæ deduced in the theoretical part of his paper, he has calculated the distribution of heat from the pole to the equator for each successive parallel, and compared it with the distribution of solar radiation. As a basis for the distribution of heat over the surface of the land, it was first necessary to determine the conditions under which the influence of the neighbouring sea is either nothing or minimal in amount. The starting-point for this was the fact that the temperatures on continents exhibit very great variations, and from these was determined for each area, as a percentage, the relative influences of the sea and continent upon its temperature. The region where the influence of the sea was proved to be nil (or where, as the speaker said, the "continentality" was 100 per cent.) was in the neighbourhood of the east coast of Asia, whereas all other points were found to be affected by the neighbouring sea to a greater extent; the observed temperature on the land was therefore only partly dependent upon the position of the place on any given parallel, other influences making themselves more or less felt. Hence it was possible to calculate for each parallel the real and "accessory" temperature. The amount of heat radiated down from the sun was compared with these temperatures, and was found to be about the same for each 10° C. of difference in temperature; from 0°–10° C., however, quite considerable differences of radiation were necessary. In conclusion, Dr. Zenker compared the temperatures which really exist on the earth's surface with those which he had deduced, and found that in reality the climate on the sea of the southern hemisphere is colder than it should be according to calculation—a result which must be attributed to the oceanic currents of cold water. The continental climate in the northern hemisphere is slightly too warm, in consequence of the disturbance introduced by the Gulf Stream.—Lieutenant Moedebeck gave an account of a balloon journey which he made on March 31. The marked phenomenon during the same was the influence of rivers; thus, after the balloon had risen to a height of 300–500 metres, and was passing away over Berlin, it sank so rapidly over the Spree that when it was about 50 metres above the earth a large quantity of ballast had to be thrown out. At an elevation of 1200 metres he met with a long narrow rain-cloud, in passing through which the dry-bulb thermometer registered 1°·5 C., the wet-bulb 1° C.; at an elevation of 1300–1400 metres, both thermometers recorded the same temperature of 2°·5 C. At this height, and in circumscribed areas, a few very small semi-soft hailstones were observed. Shortly after this the balloon began to sink, and while still above the cloud, but at a lower level, somewhat larger but similar hailstones were observed for the second time. As soon as the balloon had passed through the cloud, rain fell for a short time, as the result of which the balloon was so weighted that it descended rapidly to the earth. The atmosphere above the cloud was not clear but rather misty.

FLORA OF THE HAWAIIAN ISLANDS.

Flora of the Hawaiian Islands; a Description of their Phanerogams and Vascular Cryptogams. By William Hillebrand, M.D. Annotated and Published after the Author's death by W. F. Hillebrand. 8vo, pp. 673, with Frontispiece and Four Maps. (London: Williams and Norgate, 1888.)

THE Sandwich Islands, from a botanical point of view, are a group of peculiar interest. There are about a dozen of them, and they form an area of which the northern end falls just within the tropical zone, at a distance of 2000 miles from America, and separated from it by a deep gulf. From the nearest points of Polynesia proper, the Marquesas Islands and Tahiti, they are distant 1860 and 2190 miles. The largest island, Hawaii, is the most southern of the group. It has an area of about 5000 square miles, and its mountains, one of which is an active volcano, rise to a height of nearly 15,000 feet. The other islands, all taken together, are not equal to more than half the area of Hawaii. The capital of the group, Honolulu, is situated on the south side of the small island of Oahu. The average annual temperature of Honolulu is 75° F., the general range of the thermometer being from 70° to 83°, so that within an area about equal to that of Yorkshire we have every variation of temperature from equatorial heat to perpetual snow. Dr. Hillebrand estimates the total flora of the islands (Phanerogamia and Vascular Cryptogamia) at 999 species, representing 365 genera, and 99 orders. Of these 999 species, 653 are absolutely restricted to the Sandwich Islands, 207 native species are known elsewhere, 24 species were introduced by the natives in remote times, and 115 species are weeds of recent introduction. Leaving the introductions out of account, we have therefore a native flora of 860 species, of which three out of four are endemic. A vegetation thus individualized makes the group one of the most interesting fields of study in the world.

Dr. Hillebrand may be said to have devoted his life to the study of this question. He was born in Westphalia in 1821, and studied medicine at Göttingen, Heidelberg, and Berlin. After taking his degree, he settled down for a short time in practice in Germany, but his health soon broke down, and he sailed for Australia. After visiting the Philippine Islands and California, he made the Sandwich Islands his home, and his health became quite restored. He lived at Honolulu, mastered the language, and practised his profession with great success. He became private physician to the king, a member of the Privy Council, an active member of the Board of Health, and physician to the Queen's Hospital and the principal lunatic asylum. During twenty years he devoted his leisure to working out the botany of the group, and sent large collections to Kew and other European herbaria. He left the islands in 1871, but kept up a regular correspondence with various residents who were interested in botany, and who sent him further collections. He died in July 1886, just after completing the descriptive portion of this present work, which has been edited by his son, who lives in America, and who has prefixed to it the introduction which was drawn up by Mr. Bentham for our British colonial floras. His name is commemorated by the genus *Hillebrandia*, which is the only representative of the *Begoniaceæ* in Polynesia, and which was named after him by Prof. Oliver. The type specimens of the present work have been presented to the Berlin Herbarium, and the Prussian Government has made a grant towards the expense of its publication.

The book, which is dedicated to the Hawaiian people, consists almost entirely of careful descriptions, in English, of the orders, genera, species, and varieties, that form the flora, accompanied by full details of their distribution through the different islands, and the sort of places in which they grow. Nearly all the native plants are trees, shrubs, or perennial herbs. Comparing the islands with one another, Dr. Hillebrand's general view is that the flora of Kaui, the comparatively small north-eastern island of the group, is the richest and most individualized, and that of the large southern island of Hawaii, where the mountains rise the highest, is the most monotonous and least attractive. The total number of species here described as new is 180, but in some cases, as, for instance, by Mr. C. B. Clarke, in his "Monograph of the Cyrtandraceæ," issued in 1883, the publication of these has been anticipated, and the earlier names will have to be adopted. It is much to be regretted that the author did not live to work out fully his generalizations. A great deal has been written during the last few years on the general subject of plant-distribution, and in particular Wawra and Engler in Germany, and in England Wallace in "Island Life," and Hemsley in the "Botany of the *Challenger*," have discussed the various points of interest connected with the flora of these islands. What is wanted now is that Dr. Hillebrand's added facts should be compared together and summarized, and that the general conclusions which they establish should be carefully traced out.

The following is his outline of the zones of vegetation and their characteristics:—

"(1) *The Lowland Zone.*—Open country, grass-covered after the rains, with isolated clumps of trees, represented by *Paritium tiliaceum*, *Erythrina*, *Reynoldsia*, *Pandanus*, *Capparis*, *Gossypium*, *Abutilon incanum*. This includes also the littoral zone.

"(2) *The Lower Forest Zone.*—Tropical in character, its upper limit between 1000 and 2000 feet above the sea. Its physiognomy is marked distinctly by *Aleurites moluccana*, the pale foliage of which, in contrast with the green colour around, attracts at once the eye of the beholder. The woods are rather open; *Zinziber Zerumbet* covers the ground. *Cordyline*, *Eugenia domestica*, *Zinziber Zerumbet*, and other species, are strictly confined to it. *Pandanus odoratissimus* and *Paritium tiliaceum* do not pass beyond it, but *Freycinetia* does. To its upper portion, but extending also into the lower part of the next zone, belong also most *Sapotaceæ*, *Apocynaceæ*, *Gardenia*, *Psychotria*, *Maba*, most *Urticaceæ*, *Pisinia*, *Elæocarpus*, *Aurantiaceæ*, and others.

"(3) *The Middle Forest Zone.*—This lies within the region of clouds, and develops the greatest luxuriance in trees and jungle. *Pelea* and *Cheirodendron* are representative genera. The prevailing trees are indeed *Metrosideros polymorpha* and *Acacia Koa;* but, although they reach here their greatest development in size and number, they are not confined to this zone, but ascend above and descend below it. It is the home of all Rutaceous and most Araliaceous trees, the ubiquitous *Dodonæa viscosa*, *Alphitonia*, and *Coprosma*. The ferns luxuriate in it, and tree-ferns attain only here their full dimensions. Old trunks are wrapped in creeping ferns, mosses, and lichens. Here also the *Lobeliaceæ*, the peculiar pride of our flora, exhibit their most striking forms, invariably in isolated individuals. The upper limit of this zone may be drawn at an elevation of 5000 to 6000 feet.

"(4) *The Upper Forest Zone.*—This extends as high as 8000 to 9000 feet, and is characterized by stunted trees, chiefly *Sophora chrysophylla*, *Cyathodes*, *Myoporum*, arborescent *Raillardiæ*, *Wikstromiæ*, and *Coprosma Menziesii*. Between them luxuriate shrubby *Compositæ* (*Raillardia*, *Dubautia*, *Camphylotheca*, and *Artemisia*), with strawberries, brambles, and *Vaccinium*. Ferns are scarce, and mostly belong to widely spread species .Our shrubby *Geraniums* and silvery-leaved *Argyroxiphium* extend beyond this zone to the upper limit of vegetation, which on Mauna Kea may be placed at 11,000 feet. *Santalum* belongs to this zone and the upper levels of the last.

"(5) A place apart must be assigned to the bog flora of the high table-land of Kaui and the broad top of Mount Eeka, on West Maui. The turfy soil is covered with tussock-like *Gramineæ* and *Cyperaceæ*, all endemic species, with *Sphagnum*, creeping forms of woody *Metrosideros*, *Cyathodes*, *Geranium*, *Lysimachia*, and a number of rare, mostly single, representatives of genera which have their home in the Antarctic regions, New Zealand, the Falkland Islands, and the Southern Andes."

As a whole the flora of the Sandwich Islands stands out remarkably isolated from those of the two nearest great botanical regions, Polynesia and Central America, and has curious affinities with those of Australia, North America, the north temperate zone of the Old World, the Mexican highlands, the Andes, and the Antarctic regions. The subject is well worth working out in the same thorough way in which Sir J. D. Hooker has dealt with the floras of Tasmania and New Zealand.

Dr. Hillebrand's book is also valuable as a contribution to the study of varieties. In the Sandwich Islands we get a comparatively small number of species, that have lived for a long time in a country where there are great variations in temperature and humidity and little interference from man. In many of the endemic genera the species are very difficult to individualize, and he has named and characterized a great number of varieties. Altogether the book is of exceptional value, not only to the systematic botanist, but to all who are interested in the problems connected with the origin and distribution of species.

J. G. BAKER.

THE GEOLOGICAL EVIDENCES OF EVOLUTION.

The Geological Evidences of Evolution. By Angelo Heilprin, Professor of Invertebrate Palæontology at the Academy of Natural Sciences of Philadelphia. (Philadelphia: Published by the Author, 1888.)

FEW chapters in the "Origin of Species" are more impressive, from their perfect candour and their far-sighted prescience, than those dealing with the objections which might be urged against the author's hypothesis, on the ground of the comparatively small palæontological evidence in its favour. But this evidence, as every student knows, has been almost surprisingly strengthened and augmented during the thirty years which have elapsed since the publication of Darwin's great work. It is, however, owing to the nature of the case, scattered up and down various scientific periodicals, many of which are practically inaccessible to the general public, so that both its amount and its force are under-estimated, and the old objections are confidently reiterated by that still numerous class to whom "Darwinism" is a bugbear, and the very name of "evolution" an absolute abomination. As Prof. Heilprin states in his preface, "There has not thus far appeared, to the knowledge of the author, any collective or consecutive statement of the evidence which geology and palæontology present in support of organic transmutation;" so "with the view of partially filling this gap in the literature of Darwinism, the author has prepared, at the request of many of his friends, the following pages, which represent, somewhat broadened, the substance of a Friday evening discourse delivered at the Academy of Natural Sciences of Philadelphia." Thus this little book, while scientific in conception and method, is popular in style. While there is no attempt at an appeal to prejudices, scientific terminology is as far as may be avoided, and the illustrations appended enable any reader, with a very moderate knowledge of natural history and palæontology, to comprehend the line of reasoning followed by the author.

It is needless to add that he is a thorough going evolutionist, though, like his master, he is candid in admitting defects in the record, and transitions which as yet are merely hypothetical. In one case, however, he ventures on a statement which seems to us over bold: "It is not my purpose to-night to discuss the status of evolution, which has long since passed from the realm of pure and simple theory, but to present to you such of the more salient facts bearing upon its proof, drawn from my own department of geology and palæontology, as will permit you to understand why the greater number of naturalists consider the doctrine as firmly established to-day as is the Copernican theory of planetary revolution, the theory of gravitation, or the undulatory theory of light."

We cannot but think that, in making this confident assertion, Prof. Heilprin has exposed a joint in his harness to the arrows of his adversaries. In years to come, evolution, as stated by Darwin, may assume, probably will assume, the position of the above-named theories in physical science, but surely the evidence for it is not yet either so complete or so conclusive as for them. Hence it is unwise thus abruptly to exclude any possible modification or supplement. In scientific arguments it is better not to imitate the practices of political orators, but to err, if at all, on the side of understating rather than of overstating a conviction, and to impress by caution in reasoning rather than to dazzle by rhetoric.

This, however, is a matter of opinion: we pass on to indicate briefly the line of argument followed by Prof. Heilprin. At the outset he calls attention to two misconceptions relating to evolution which are widely prevalent, and are often made the ground of assaults upon the hypothesis. These are: that if the missing forms of life could all be recovered, they would form a continuous chain, and that "the progressive modification of individual organic forms need be, or indeed has been, one of continuous advance." Past and present organic life, as Darwin himself carefully pointed out, are combined, not in a continuous chain, but in a genealogical tree: "evolution recognizes modifications in the most divergent directions, and the tree of life that it restores is not a straight stem growing from a continuous apical bud, but a stem, or possibly even a limited number of stems, branching in varying directions." Thus the progress among organic beings is analogous to that in the development of civilization. "The united world advances, whereas individual tribes or nations remain at a standstill, or even degenerate and decay. Such is precisely the history of the organic development of our planet: new and more complicated organic types are being continually evolved, but side by side with these forms we still meet with those of a lower grade of organization, while still others, belonging to the earlier periods of the world's history, have completely dropped out."

After a brief sketch of the first appearance of vertebrate life, Prof. Heilprin describes the relations of the fishes, the amphibians, and the reptiles, indicating the affinities of the first and second, which have led Prof. Huxley to treat them as sub-groups of a single division, the Ichthyopsida. In the structure of the heart, mode of breathing, and nature of circulation, the young frog agrees with a fish, while in these respects the mud-fishes (*Ceratodus*) agree with the amphibians. Now this link between these great groups exists in very early times, as the hypothesis would demand. "Dipterus and its allies are fishes that belong to the Devonian period of time," and Ceratodus itself was living in the Permian, and thus "represents the oldest living vertebrate type known to naturalists." The peculiar structure of the teeth of the labyrinthodonts, found also in some of the earliest fishes, and still retained by the alligator-gar, is another link. Next, in regard to the date of the appearance of birds and mammals, which is sometimes regarded as rather anomalous, Prof. Heilprin points out that both the earliest birds and the earliest mammals have marked reptilian affinities, which in the former are very distinct, so that such forms as *Archæopteryx* and some of the early dentigerous birds on the one side, and the *Pterosauria* on the other, do much to link together the two classes. Further, the ancestry of the non-flying birds, such as Dinornis and its allies, may be traced with greatest probability to members of the Dinosauria, such as Iguanodon, Hadrosaurus, and Compsognathus. In like way the affinities of the monotremes with the reptiles are pointed out, and attention is called to the significant fact that "the earliest reptilian forms—those of the Permian period—are the only animals which possess the remarkable dental characters of the Mammalia."

In the second section of the book Prof. Heilprin deals more especially with the development of the Mammalia themselves, instancing the position occupied by the Eocene *Creodonta* between the now widely divergent *Carnivora* and *Insectivora*, the relationships among the groups of the former, and of the latter to the lemurs, the well-known pedigree of the horse, the ancestry of the hornless ruminants, the development of the horns of the deer, from the simple forked crown in the early Cervines of the Middle Miocene to the complicated forms assumed in the Pliocene and more recent times. *Cervalcas americanus*, the newly-discovered link between the Canada stag and the elk, also receives notice, as does the relation of the homocercal and heterocercal to the primitive diphycercal fishes. Attention is also called to the development of the brain in various vertebrates.

In the third section the author glances at the question of the antiquity of man. In regard to some of the alleged evidence he exercises a wise scepticism, and states that up to the present time he has been unable "to find satisfactory proof of man's belongings having been found in deposits very much (if at all) older than the Post-Pliocene," though he thinks it not unlikely that such may ultimately be found. In connection with this subject he mentions some human vertebræ, mineralized by limonite, of unknown but evidently high antiquity, discovered by himself in Florida.

Lastly, he calls attention to a class of evidence which the comparative persistency of conditions in certain parts of the United States has rendered accessible to American geologists—namely, the relation of living forms to their more immediate predecessors. Instances of this may be obtained in the sheltered regions of the Gulf of Mexico and in the comparatively modern rocks of the Florida peninsula. As examples, species of the genera *Strombus*, *Voluta*, *Fulgur*, and *Melongena*, are figured, showing the gradual transition from an extinct to an existing species, and to these are added a group of Paludinæ from the Middle Tertiary of Slavonia, illustrating successive varietal and specific forms.

The book is attractively written, though we must venture to protest against two instances of American-English: "The swift-footed animal . . . elevates the body so as to *weight* it principally upon the extremities of the toes;" and "the evidence is . . . but a mere *figment* of that which pertains to zoology." The first gains so little that brevity can hardly be pleaded as its excuse; the second, unless a misprint, is worthy of Mrs. Malaprop. T. G. B.

THE SHELL-COLLECTOR'S HAND-BOOK FOR THE FIELD.

The Shell-Collector's Hand-book for the Field. By J. W. Williams, M.A., D.Sc. Small 8vo, pp. 148 (interleaved). (London: Roper and Drowley, 1888.)

HANDY books for collectors, whether of birds, beasts, fishes, mollusks, or other organisms, are always most acceptable when well put together and carefully contrived, even if they be not original. The present little book might at first sight lay claim to having fulfilled all these conditions. It is small enough for the pocket, and the type is clear and legible; but when we enter upon the work itself, alas! we do not find our dream of a typical collector's hand-book realized by any means. Chapter I. "The Anatomy of a Snail," and Chapter II. "The Anatomy of a Fresh-water Mussel," should have been altogether omitted. They are not cleverly compiled, they are sadly full of mistakes, and these too clearly betray the fact that the author himself is not familiar with Mollusca from an anatomical point of view, but rather has got up his subject after the style of "Cousin Cramchild." Thus, the *colour* of the shell (says Dr. Williams), *exists entirely* in the *periostracum* or *epidermis*. We would advise the learned author to try and remove the epidermis from a snail-shell and observe the result.

The lip or aperture of a snail's shell is not generally called the *peritreme* but the *peristome*. The lines of growth in a snail's shell are not "arranged *concentrically* with the *nucleus*," although this is the case with the growth-lines in bivalves.

We fail to understand how the *operculum* of a snail "differs from the true shell in having more *conchiolin* entering into its composition." Surely the author meant to say *less conchiolin* and *more chitine?*

The *epiphragm*, or layer of hardened mucus, sometimes strengthened with carbonate of lime, closing the aperture of the shell of land-snails during hibernation is called here also the *clausilium!* (p. 5). The description of the odontophore with its radula and jaws (pp. 6 and 7) is very inaccurately rendered, and in copying Prof. Lankester the author has carefully also quoted a mis-statement as to the formula of the teeth.

The eggs of snails are said by the author to be "laid in a string, which is called the *nidamental ribbon*, or inclosed in *horny capsules*." This is true of sea-snails, such as the whelks (*Fusus*, *Buccinum*, &c.), but it is not the case in land-snails, of which Dr. Williams is discoursing. In these the eggs are separate and protected by a shell, which is sometimes membranous and flexible, at others calcareous and brittle, while those of the fresh-water species are deposited in small glairy masses of soft transparent jelly-like consistence.

Turning from the snail to the fresh-water mussel (Chapter II.), the author, in describing the animal of the latter, appears to have made a mistake similar to that which he has made with regard to the garden snail: not knowing his subject well, he has in fact described a *siphonated Mya*, when he fondly imagined he was writing about a *non-siphonated Unio* or *Anodon*.

Turning to the species enumerated by the author, we regret to observe that here the discrimination of the expert is alike wanting. For example, *Anodonta anatina*, Linn., figures as a good species, whereas it is merely a variety of *A. cygnea*, Linn. It seems rather absurd to give in a shell-collector's hand-book such shells as *Physa acuta*, Drap., "Hab. In one of the lily-tanks in Kew Gardens, imported" (p. 72); *Bulimus Goodallii*, Miller (introduced into a green-house with exotic plants); *Vertigo tumida*, Westerlund, another "casual"; *P. dilatatus*, Gould, in the canals around Manchester, "introduced from America in cotton bales." If these are admitted, why omit *Clausilia parvula* and *C. solida*, also "casuals," which appear both in Sowerby's last edition, and in Gwyn Jeffreys, v. 161–62?

Far too much prominence is given to worthless varieties of the common snail *Helix aspersa*, such as *minor*, *maxima*, *albida*, and *sinistrorsum*, &c.; but, having put them in, why should the author omit such a one as *Unio timidus* var. *ponderosa?* Many of the genera, too, need revision to be brought up to date. Thus, *Achatina acicula* should be *Cæcilianella acicula; Bulimus acutus* should be *Helix* (*Cochlicella*) *acuta; Zonites* should be *Hyalinia*. By the way, *Zonites draparnaldi* is omitted altogether, although known for years.

The habitats of many of the species are badly given. Thus, *Testacella Maugei* is said to be found in gardens and fields, whereas it has been met with in the neighbourhood of Bristol, whence it has spread to a few limited localities.

Why are the three known localities for *Vertigo moulinsiana* (p. 129) omitted?—Itchen Valley, near Otterbourne; near Hitchin; and near Rye-House, Herts. Other quite local species are recorded as if they occurred everywhere, as *Helix pisana* and *H. obvoluta*, &c.

A few woodcuts are inserted, but they are very poor and not accurately drawn. *Testacella haliotidea* is reversed.

The minute characters of the shells, so useful in many instances in the field, are omitted. The book is interleaved, which doubles its thickness for field-work, and we at first wondered why so much plain paper was added. It has since occurred to us that the author had the convenience of the reviewer in his mind's eye, and we must say we found the blank pages most useful in correcting the text as we turned over the leaves.

Is it too much to hope that the author may be able to give some attention to the living land and fresh-water Mollusca before he brings out a new edition of his handy shell-collector's manual, and so avoid those pitfalls into which he who compiles unskilfully and without practical acquaintance with his subject is sure to slip?

OUR BOOK SHELF.

A Text-book of Biology. By J. R. Ainsworth Davis, B.A., Lecturer on Biology in the University of Wales, Aberystwith. (London: Griffin and Co, 1888.)

THIS is one of a class of books which the system of examining the whole world on a limited schedule, drawn up by a Board of disinterested philanthropists, is bound to produce. It will delight the misguided student whose sole desire is "to get through" with the least knowledge possible, and will disgust every competent teacher. Mr. Davis is in error in stating that his book supplies a gap in literature. The little text-book by Prof. Lloyd Morgan is on the same lines, and appears to us to be far less objectionable, inasmuch as it is, though of smaller dimensions, a more genuine exposition of the principles of the subject, less of a cram-book than the present work, and written with maturer judgment and literary power. The only way to prevent the study of biology, as directed by the University of London, from sinking into a worthless exercise of memory applied to the contents of such little books as this by Mr. Davis, is to change the animals and plants enumerated in the schedule every three years. This, however, would hardly suit the ubiquitous aspirants to a degree for whom alone the Imperial University arranges its curriculum. Nor would it suit Mr. Davis and other more distinguished authors of regulation cram-books. The fact is that genuine education in biology as a science, and the influence of personal contact and association with an active investigator and discoverer as teacher and friend, are destroyed by the Imperial system of schedule and examination; and their place is taken by weary grinding at little books written by teachers of no authority, and too often ignorant as well as unintelligent.

Mr. Davis has borrowed a number of excellent figures to illustrate his book, which is nothing more nor less than a strictly limited, and in minor points an inaccurate, description of the types named in the schedule of the University of London. The new figures are bad, and the short general introduction is not merely shallow but erroneous, *e.g.* the account of protoplasm and the tabular statement of differences between plants and animals.

Reports of the Geological Survey of New Zealand.

THE issue of an index to the Reports of the Geological Survey of New Zealand, from 1866 to 1885 inclusive, enables us to see at a glance how large an amount of valuable material has been accumulated by the staff of this Survey, under its accomplished and energetic Director, Sir James Hector. Several editions of the useful geological map of the colony have appeared, the latest dated 1885; and the volumes containing the yearly reports of progress are now eighteen in number. Monographs on the palæontology of New Zealand are stated to be in preparation, and there are, besides these, museum and laboratory reports, meteorological returns, and miscellaneous publications. The difficulties felt in correlating the strata of so isolated an area as New Zealand with the rocks of other districts must always be very great, and it is therefore not surprising to find that warm and animated discussions are taking place among the different geologists of the colony as to the age and relations of some of the fossiliferous deposits. We may feel assured that the solution of these questions will be fraught with important results having a direct bearing upon some of the most difficult problems that now confront geologists.

First Lessons in Geometry. For the Use of Technical, Middle, and High Schools. By B. Hanumanta Rau, B.A. (Vepery: Printed at the S.P.C.K. Press, 1888.)

THIS is a second edition, revised and enlarged, of a very good book for those who are beginning the study of geometry. Much stress is laid all through on the construction and careful drawing of the figures, and great pains seem to have been taken by the author to make his meaning as clear as possible by means of simple examples, thereby inducing the reader not to learn the propositions by heart.

The volume is well arranged as regards the order of the subjects, and teachers, as well as taught, will find in it a good amount of useful information.

LETTERS TO THE EDITOR.

Dissemination of Plants by Birds.

I FULLY agree with Dr. Guppy that birds may have effected much more in the distribution of plants than is generally admitted, and I think it is most desirable that his suggestion respecting the examination of the contents of the crops of birds shot at sea in high southern latitudes should be carried out. At the same time I am of opinion that his explanation of the probable origin of the vegetation of the distant islands in the South Atlantic and South Indian Oceans is insufficient to account for the endemic element, unless we suppose a former belt of vegetation in a higher latitude than these islands, which is now extinct. Assuming the existence of such a belt of vegetation at some remote period, it would not be difficult to explain the relationships between the floras of America and Australasia, as well as the presence in these islands of plants not known to exist elsewhere.

Pringlea antiscorbutica, the Kerguelen cabbage, is the most remarkable of the endemic plants. As a genus, it is as well characterized as the majority of the genera of the Cruciferæ; but, what is more significant, it has no near ally in the southern hemisphere, being most nearly related to the northern genus *Cochlearia*, differing from it more in habit of growth than in any structural peculiarity. It is one of the commonest plants in the islands, from Prince Edward Group to the Macdonald Group, and produces seeds in great abundance.

Lyallia kerguelensis is, so far as is known, confined to Kerguelen Island. It is one of the degraded types of the Caryophylleæ-Polycarpeæ, and nearly related to the Andine genus *Pycnophyllum*, and the North Mexican genus *Cerdia*.

To my mind there are other difficulties in the way of such a derivation of this insular vegetation as that suggested by Dr. Guppy, but I will not enter into them here, as it would occupy too much space. W. BOTTING HEMSLEY.

On the Reappearance of Pallas's Sand Grouse (*Syrrhaptes paradoxus*) in Europe.

THIS bird suddenly reappeared at the end of April of this year at different localities of Central Europe, not having migrated so far since 1863. A. R. Wallace, in his important work, "The Geographical Distribution of Animals," published in 1876, figured this sand grouse among the characteristic birds of Mongolia (vol. i. p. 226, plate 3), and remarks:—"A curious bird, whose native country seems to be the high plains of Northern Asia, but which often abounds near Pekin, and in 1863 astonished European ornithologists by appearing in considerable numbers in Central and Western Europe, in every part of Great Britain, and even in Ireland." Vol. ii. p. 337, the same author says in the work quoted:—"*Syrrhaptes* normally inhabits Tartary, Thibet, and Mongolia to the country around Pekin, and occasionally visits Eastern Europe. But a few years back (1863) great numbers suddenly appeared in Europe, and extended westward to the shores of the Atlantic, while some even reached Ireland and the Faroes."

Mr. Wallace, speaking here of the geographical distribution of *Syrrhaptes*, has in view the two species of the genus, viz. *S. paradoxus*, Pallas, from Tartary and Mongolia, and *S. tibetanus*, Gould, from Thibet; whereas in the following sentence, treating of the extraordinary migration, only *S. paradoxus* appears to be meant. At least I am not aware that the second species has ever been observed in Europe.

Two years later not one bird of those that immigrated in 1863 appears to have been observed again here; they may have died, or been cruelly killed, or may have returned to their native steppes. No special notice having been taken of their movements, we did not learn the reason of that uncommon migration, nor the rapidity of their wandering, nor whether they returned to Asia or not.

The reappearance of the sand grouse in large flocks, consisting apparently of innumerable individuals, now gives us the opportunity of watching their movements in detail. This should be done everywhere, and for this reason I communicate the following notes, comprising all that I have learned till to-day about it. I am sure that many more observations will have been made in these days, and perhaps those who can add something to the following list will do so through the columns of NATURE. Observers should especially try to find out whether there are specimens of *S. tibetanus* among them.

April 21, Plock, Poland. On the same day specimens on the River Pilica, near Radom, and in the market of Warsaw, Poland.
,, 24, at 5 p.m., near Pirna, Saxony.
,, 25–26, in the night, near Leipzig, Saxony.
,, 26, Kalisch, Poland.
,, 27, 3 p.m., near Grossenhain, Saxony; on the same day several flocks there.
,, 27, 4 p.m., near Pirna, Saxony.
,, 27, Brandenburg, Prussia.
,, 27, Elbing, Prussia.
,, 27, near Leipzig, Saxony.
,, 28, near Leipzig, Saxony.
,, 28, Kuchelberg, Silesia.
,, 28, Czerwinsk, Poland.
,, 28, Warscha, Poland.
,, 29, Cernowitz, Bohemia.
On the last days of April near Görgény, Transylvania, and near Königstein, Saxony.
May 1, near Grossenhain, Saxony.
,, 1, Liobschütz, Saxony.
,, 1, Niederfaulbrück, Silesia.
,, 2, Ratzeburg, Holstein.
,, 2–3, in the night, near Grossenhain, Saxony.
,, 3, near Grossenhain, Saxony.
,, 3, near Bautzen, Saxony.
,, 3, near Schneeberg, Saxony.
,, 3, near Friedeberg, Silesia.
,, 4, near Grossenhain, Saxony; several flocks.

May 5, 4 a.m., near Grossenhain, Saxony.
,, 5, Island of Rügen, on the Baltic.
,, 6, near Freiberg, Saxony.
,, 6, near Königstein, Saxony.
,, 6, near Rendsburg, Holstein.
,, 7, Reichenau, Saxony.
,, 7, near Soldin, Brandenburg, Prussia.
,, 7, Palczyn, Posen, Prussia.
,, 7, near Leipzig, Saxony.

Royal Zoological Museum, Dresden, May 12.

"Coral Formations."

IN a recent paper read before the Royal Society of Edinburgh, I have pointed out the importance of taking into consideration the molecular condition of carbonate of lime in relation to its solubility in sea-water.

The (tabulated) results of an exhaustive series of tests (see NATURE, vol. xxxvii. p 605) show in a striking manner this difference between the crystalline (or massive) and the amorphous conditions of that body.

In Table II. the amount of carbonate of lime taken up by sea-water from decomposing shell-fish is shown to be very great, the clear newly filtered solution giving 0·384 grammes per litre (other determinations since made giving still higher results); this is due no doubt to the formation of carbonic acid, the result of the oxidation of the organic matter in the putrefying mass.

The clear (foul-smelling) liquid on standing exposed to the air rapidly decomposes, ammoniacal salts being formed; and a great portion of the amorphous carbonate of lime which was dissolved during the first stages of putrefaction is thrown out of solution and deposited in a crystalline and practically nearly insoluble form.

This may be due to the loss of carbonic acid, or its combination with ammonia, produced during decomposition of nitrogenous organic matter; or to the well-known action certain salts of ammonia (especially the carbonate) exert in degrading the solubility of carbonate of lime in water; but the result so produced, I think, meets all the objections Mr. T. Mellard Reade brings forward against the solution theory, which is Dr. Murray's explanation of the formation of coral lagoons.

Again, when a clear saturated solution of amorphous carbonate of lime in sea-water (see Table II., *a* and *b*) is allowed to stand for a few hours at ordinary temperatures, the solution becomes turbid and ultimately throws out in a crystalline condition a considerable proportion of the carbonate of lime it held in solution.

Dr. Murray, in a paper on "Structure, Origin, and Distribution of Coral Reefs, &c.," read before the Royal Institution, London, on March 16, refers to this change of condition as follows:—

"The whole of a coral reef is permeated with sea-water like a sponge; as this sea-water is but slowly changed in the interior parts it becomes saturated, and a deposition of crystalline carbonate of lime frequently takes place among the interstices of the corals and coral debris."

These facts seem to me quite sufficient to account for the formation of coral lagoons by the more rapid solution of the amorphous form of carbonate of lime, found in dead and decomposing corals. At the same time other deposits are preserved from wholesale solution by the change in the molecular condition which carbonate of lime undergoes,—always the after result of solution.

I need not here refer to other influences at work in maintaining the balance of absorption and secretion of lime salts in the ocean, because I consider the difference in solubility of various forms which carbonate of lime assumes equally accounts for the formation of lagoons and the preservation of coral reefs and shell beds or banks.

ROBERT IRVINE.

Royston, Granton, Edinburgh, May 14.

Aurora Borealis.

THE aurora borealis was visible here on Sunday night, May 6. We have difficulty in identifying it in this neighbourhood without spectroscopic aid, because the lights of Liverpool and its suburbs extend over the eastern horizon, and the sky to the north-east and north is filled with a glow from Bootle and Birkenhead, these several lights often giving, with clouds of varying height, effects resembling northern lights.

On Sunday night, at 1.30, the brightness in the north-western sky was not to be mistaken; and shortly before 2 o'clock a curved bluish-white beam—two brilliant sides inclosing a still brighter rounded angle of about 70°—shot up from the west, the apex coming first, and attaining a height of 60°, the sides there being about ½° broad; the extremities of the sides, 1° broad, touching the horizon in the north-north-west and south-south-east. This beautiful beam remained a few seconds, then went as it came, the apex disappearing last. The general phenomenon seemed to increase in brightness, but subsequent observations show that it could not then be satisfactorily distinguished from the early dawn and reflected lights.

Rock Ferry, May 11.

Weight and Mass.

THE *weight* of a body is the quantity which is measured out by the operation of *weighing*. To *weigh* a body it is placed in one of the scales of a balance, and equilibrated by standard *weights* formed of lumps of metal called pounds, hundredweights, tons, &c., or kilogrammes in the metric system; and the sum of these weights is (*pace* Mr. R. E. Baynes) called the *weight* of the body.

The mathematician may now call this quantity, if he likes, the *mass* of the body; but the world at large uses the word *weight*, with the advantage of having the corresponding verb "to weigh," which the substantive "mass" does not possess: we are not yet accustomed to speak of a body "massing" 100 tons. The numerous circumlocutions to express one single idea in Prof. MacGregor's examples arise from the want of the verb "to mass."

The "extraordinary and peculiar" language is, then, that of the elementary text-books of Mechanics, which tell us that the *weight* of a body is the *force* with which it is attracted by the earth (Lodge, "Elementary Mechanics," p. 66).

It is true, as Sir Philip Magnus points out in his "Mechanics," § 46, that the word *weight* is made to do double duty, sometimes standing for *force* and sometimes for *mass*; and that these two significations must be carefully distinguished.

But the "ordinary he or she" would no more accept the "pull or heft required to lift a body" as a correct measure of the weight, than the Red Indian of to-day would accept the weight of the Hudson Bay factor's fist as one pound.

The theorist must then exert his ingenuity to invent a new word to express the *force* idea, to associate with the word *mass*, already invented by him; but to attempt to restrict the meaning of the word *weight* in a manner not usual in ordinary language can only lead to confusion. In any engineering, chemical, or ordinary journal we shall always find *weight* used in the sense of *mass*, as defined in the text-books of elementary dynamics; and even in these treatises we shall find in the parts on Statics the word *weight* used in its ordinary sense. For instance, on p. 196 of Dr. Lodge's "Mechanics," we find, Ex. 10, "A mass of wood (sp. gr. 0·6) is counterpoised by 105 correct grammes of iron (sp. gr. 7·5); find the mass of the wood (or its true weight *in vacuo*)."

Sometimes it is not possible to employ the balance to estimate the weight (or mass) of a body; as, for instance, when the chemist evolves a certain *weight* of hydrogen in a chemical combination, when the artillerist speaks of a gun *weighing* 110 tons, and when the astronomer "*weighs* the earth,"—in such cases the weight or mass, whichever it is called, is calculated as the product of the volume and the density: determine for example the weight of 1000 cubic feet of steel. The weight W (or mass M) is then found theoretically from the formula W (or M) $= \rho V$, but really practically from the formula $W = 62{\cdot}4sV$, where W or M is given in pounds, when V is given in cubic feet, and ρ is then called the density, and s the specific gravity (the *density relative to water*), and it is the specific gravity for which tables are given; but in the metric system W (or M) $= \rho V = sV$, where W or M is given in grammes, when V is given in cubic centimetres, and the density ρ, and the specific gravity s, are then the same. But turn to the ordinary text-books, and we find these confusing equations—

$$W = Mg = g\rho V = sV,$$

where W is called the weight, M the mass, ρ the density, and s the specific gravity, followed often by a series of absurd examples on changes of units.

These relations are derived from the equation $W = Mg$, the source of all confusion in Dynamics, and it is gratifying to find from Prof. Mendenhall that a crusade against it is in progress in America.

It is needless to repeat here the objections against this equation, but it is easy to see how it arose.

Mathematicians now measure mass in pounds, so that the mass of a body is the number of pounds of matter in the body (*the weight* in the vernacular); and the equation $W = Mg$ means that the weight of M pounds is Mg poundals, according to their definition that "the weight of a body is the force with which it is attracted by the earth"; but this was not so originally.

Early writers on Dynamics, before Gauss invented the absolute unit of force, always employed the statical gravitational unit, and then if a weight of W pounds was acted on by a force of P pounds, the equation of linear motion was $\frac{W}{g}\frac{d^2x}{dt^2} = P$.

To avoid the necessity of writing and printing $\frac{W}{g}$, it was replaced by the letter M, and called the *mass*; the unit of mass being thus g pounds. But now the invariable quantity, the mass, is measured in terms of a variable unit, while the variable unit of force is the attraction of the earth on a 1-pound weight.

Although such words as "a force equal to the weight of the mass of 10 pound weights" do not occur in Prof. MacGregor's book, they are strictly derived from his own definitions; and so is the following, "the weight of 32 pound weights on the Earth is at the surface of Jupiter a force of 71 pounds' weight." I bring forward these illustrations to show that the fine distinction between "10 pound weights" and "10 pounds' weight" is not workable; and to show that the addition of the word *weight* to *pounds* does *not* convey the idea of *force* in ordinary language, and is not clear even in the language of the precisionists.

Nor can the equation $p = g\rho z$ in Hydrostatics be defended, as capable of expressing a pressure in pounds on the square foot (or more commonly on the square inch); for, if Prof. MacGregor applies this equation to a numerical example, he will find himself dividing by g in one operation, only to multiply by g in the next. The unreal character of these changes of units is apparent when we come to numerical examples; the defect of our dynamical teaching is that the student is so rarely brought before a practical numerical illustration on a large scale.

The rest of Prof. MacGregor's remarks I must answer very briefly, for fear of occupying too much space.

The *kilometre* was designed to be the centesimal minute of latitude, to replace the *geographical or sea mile*, which is the sexagesimal minute of latitude; the quadrant of the earth is therefore 10,000 kilometres, or 10^9 centimetres, and $90 \times 60 = 5400$ geographical or sea miles.

The cosmopolitan unit of speed at sea is the *knot*, which is a *velocity* of one geographical mile an hour; if 10 knots, spaced about 50 feet apart, pass over the taffrail in half a minute, the vessel is said to be going 10 knots. All civilized nations measure speed at sea in *knots*, in French *nœuds*, German *knoten*, Dutch *knoopen*, Italian *nodi*, Spanish *nudos*, &c. In precision *knots an hour* is on a par with *atmospheres per square inch*.

It is unfortunate that we have not yet reached uniformity in the use of the words *elongation* and *extension*. The French treatises, and our practical writers, Rankine, Unwin, &c., use *tension* and *extension*, *pressure* and *compression*, to denote simple longitudinal stresses and their corresponding strains; the ratio of *tension* to *extension*, or of *pressure* to *compression*, being the *modulus of elasticity*. This variation in terminology must be settled by some arbitrator, say Prof. Karl Pearson.

In conclusion, speaking on behalf of engineers and practical men, I beg to say that the treatment of the subjects of weight, mass, and force, in our ordinary text-books of Mechanics, is by no means clear or satisfactory, and requires careful revision.

Woolwich, May 4. A. G. GREENHILL.

Density and Specific Gravity.

IF Mr. Cumming's definition of *specific gravity* be accepted, the confusion, already serious enough, in the minds of beginners in physics between mass and weight will be much increased. Surely the best and clearest definitions of *density* and *specific gravity* are those given in Glazebrook and Shaw's "Practical Physics," p. 105. These make *density* a quantity having dimensions in mass and space, and *specific gravity* a pure number. There are many advantages in defining *specific gravity* as a ratio, and not the least among them is that the numbers in tables of specific gravities are independent of any system of units, while in a table of quantities having dimensions the numbers given depend on the system of units used. Thus the *density* of platinum would have to be given in an English table as 1343·75 pounds, or in a metrical table as 21·5 grammes. Again we should lose the very useful analogies between the definitions of *density* and *thermal capacity* and *specific gravity* and *specific heat*, to which I drew attention in a letter to NATURE, vol. xxxiii. p. 391.

Prof. Carey Foster seems to think it would be useful to have a table telling us the force with which unit volume of any body is attracted towards the earth, and that this should be called a table of *absolute* specific gravities. But I fail to see any advantage in this, for it is adding a totally new definition to be remembered, and one which would certainly create confusion in a beginner's mind; and the objection applies to this, that the numbers given would depend on the system of units used, to say nothing of the value of gravity at the place for which the table was calculated. Supposing even that the latter were ignored, it is not more troublesome to convert, with the aid of the known weight of unit volume of water, the specific gravity of any material into the weight of a given volume of it, than to convert a number given in one system of units into the number representing it in the system we may happen to be using.

If we are to take Mr. Cumming's definition as he expresses it, I would submit that a pound avoirdupois is a quantity of matter and not a force; and to say that the specific gravity of water is 62·5 *pounds avoirdupois* is simply taking the density of water and calling it specific gravity. *Pace* Mr. Greenhill and the engineers, it is hard enough to eradicate the notion that the quantity of stuff in a body and the force with which it is pulled towards the earth are one and the same without having the task made more difficult by our definitions.

50 City Road, E.C. HARRY M. ELDER.

The Cornish Blown Sands.

IN the description of the raised sea beach at Newquay, which Sir Henry De la Beche has given in his "Survey of Devon and Cornwall," he makes no reference to a curious feature observable in a part of the beach, and to which I should like to direct attention, with a view to obtaining some explanation of the cause of its formation. As far as I know, the appearance is only to be found at one spot, on what is known as Little Fistrel, to the westward of the town. It consists of a number of *cylinders* of indurated sand, separated from each other by thin walls, often only an inch or two thick, and forming the base of the cliff or bank, which is perhaps 10 or 15 feet high at the place. These cylinders rest upon a bed of rock (argillaceous slate?), which runs down from the bottom of the bank to the sea in a series of shelving ledges. The cylinders, which are locally known as *Pixie Holes*, weather out from the bank, but unfortunately few or none of them are now to be seen in a perfect state, their walls having been broken down by people scrambling up the bank, and also by quarrying operations, which I learn have recently been carried on close by. I am told that formerly the cylinders were very perfect, and often of large size; I myself have seen them, fifteen or sixteen years ago, standing up like little towers along the base of the cliff, and I have often sheltered myself perfectly from a shower of rain by standing in one and covering myself with my umbrella. I have recently had a photograph taken of the best group to be found, and a copy of this, together with a piece of the wall of one of the cylinders, is with Mr. Goodchild, of the Geological Survey, Jermyn Street, who will show it to anyone interested in the matter; the size of one of the cylinders photographed is 51 inches deep and 28½ inches in diameter.

R. H. CURTIS.

[The sand in question is well known to geologists as an example of blown sand agglutinated into a compact stone by carbonate of lime derived from the solution of calcareous organisms, which here on the surface consist largely of land-snails. The tubular cavities are no doubt due to the removal of the calcareous cement by percolating water, and are thus of the same nature as the pot-holes in chalk, and the cavernous holes and tunnels in hard limestone.—ED.]

Self-Induction in Iron Conductors.

MR. SUMPNER quotes (NATURE, May 10, p. 30), in support of the idea that iron conductors may have less self-induction than copper ones of the same dimensions, a suggestion of mine that for very feeble magnetizing forces, iron may be diamagnetic That suggestion was confessedly speculative ; its basis was the notion that the Weber-Ampère electro-magnetic molecules suffer something akin to static friction when the process of magnetization attempts to bring them into alignment. Since it was thrown out, Lord Rayleigh has proved that the susceptibility of iron is constant, and has a fairly high positive value, for magnetic forces ranging from 0·03 to 0·04 C.G.S. downwards. Below the lowest force he has investigated, it is still conceivable that there may be a change in the susceptibility, but it is extremely improbable. In all likelihood, Lord Rayleigh's straight line in the curve of B and H or of I and H extends back to the origin. This at least is certain, that if there is any region at the beginning of magnetization within which the permeability is less than unity, or even no more than unity, it must be so infinitesimally narrow that its existence has no practical interest. For such magnetic forces as act on a lightning-conductor when a discharge is passing, iron is, beyond any question, strongly paramagnetic, and the self-induction with the iron conductor consequently greater than with the copper. J. A. Ewing.

Dundee, May 11.

Notes on the Reproduction of Rudimentary Toes in Greyhounds.

At the present writing, I have under my observation a fine male, light clay-coloured, smooth haired greyhound, which at certain intervals well illustrates the reproduction of the rudimentary digits of its feet, after they have been accidentally amputated. To-day this dog has growing on the inner aspects of both its fore and hind feet, and situated some 9 centimetres above the soles, on each limb, a strong rudimentary toe. If we choose, say, this toe on the right hind foot as an example of them all, we find it to be loosely attached, rather more than a centimetre long to the base of the claw, which latter is large and strong, powerfully curved, and fully as big as any of the claws on the foot phalanges. I further find that this toe has a well-marked pad on its under side, but careful examination fails to detect any bone in the proximal joint, from which I also infer that the ungual phalanx likewise lacks one, though this is not so easily determined without cutting through the horny theca forming the claw. About four months ago this dog was coursing hares over the prairie of this region, which chances to be overgrown with a stiff growth of sage-brush, about 2 feet to 3 feet high. The wiry stems of this plant, as the dog bounded among them, snipped off all four of these rudimentary digits, close down to the leg in each case, as nicely as though it had been done with a knife, leaving linear wounds about half a centimetre long. Now, instead of the lips of these wounds healing across, as one would naturally suppose they would, they immediately form the basis, in each case, for the growth of another rudimentary clawed toe, fully as perfect as the one which originally sprang from the same site. These subsequent growths take about three months to attain their full size again, when they are very likely to be removed by a similar process, and once more grow out as before, and so on indefinitely.

From several points of view, this case, as occurring in a vertebrate so high in the scale as a dog, has interested me very much indeed, and I further find that it is no uncommon thing to meet with greyhounds that have never possessed these rudimentary pollices and halluces, and it is fair to presume that in this race they are gradually disappearing.

R. W. Shufeldt.

Fort Wingate, New Mexico, March 28.

Dreams.

In discussing the differences between dreams and real life, Schopenhauer expresses the opinion that the distinction between these two activities of our representative power consists merely in the possibility of the representations of real life being connected in an uninterrupted successive series, while dreams resemble the separate pages of a book torn asunder, and put together again in complete confusion. Some personal observations of my own do not quite agree with this view. I have watched my dreams for some years, and have remarked that many of them are connected with one another in separate series. It happens to me very often that my dreams consist of a series of representations logically developed (although sometimes the logic is absurd) from other series of representations dreamed long before. It would be interesting to know if anyone else has observed anything of this kind. A. Bialoveski.

Oostkamenogorsk, Western Siberia, April 6.

"Antagonism."

Mr. Collins (Nature, May 3, p. 7) claims that Mr. Herbert Spencer anticipated Sir Wm. Grove and Prof. Huxley in the expression of the idea of *antagonism*. I think that priority to all of them must be given to the author of Ecclesiasticus in the Apocrypha, who says (chap. xlii., verse 24), "All things are double, one against the other. He hath made nothing imperfect." Thomas Woods.

Parsonstown, May 13.

SUGGESTIONS ON THE CLASSIFICATION OF THE VARIOUS SPECIES OF HEAVENLY BODIES.[1]

V.

Classification into Species.

We are now in a position to apply all that has gone before in a summarized statement of the various spectral changes, including those connected with hydrogen, which take place not only in these objects studied by Dunér, but in those others to which I have referred as forming the true beginning of the group.

The following statement, however, must not be taken as anything else than a first approximation to the real criteria of specific differences. I am convinced that further thought is required on it, and that such further thought will be well repaid.

The Sequence of the Various Bands in the Spectra of the Elements indicated by Bodies of the Group.

In comparing the spectrum of an element which has been mapped in the laboratory with the absorption bands in the spectrum of a "star," we need only consider those bands and flutings which stand out prominently and are the first to flash out when there is only a small quantity present. Thus, in the flame spectrum of barium there is an almost continuous background of flutings with a few brighter bands in the green, and it is only important to consider the *bands*, as the flutings would mainly produce a general dimming of the continuous spectrum. In order to show at a glance what portions of the spectrum of an element it is most important for us to consider in this discussion, I have reconstructed the map of low-temperature spectra which I gave in my previous paper, with reference to those elements which are indicated in the spectra of bodies of Group II. Five orders of intensities are represented, the longest lines, flutings, or bands being the brightest. The lines, flutings, or bands in the lowest horizon, in the case of each element, are those which are seen at the lowest temperature, and which are the first to appear when only a small quantity of substance is present. Those in the upper horizons are the faintest, and are only seen when the temperature is increased, or a considerable amount of the substance is volatilized. The map shows that if there are any indications of magnesium, for instance, in bodies of low temperatures, the fluting at 500 will be seen, possibly without the other flutings or lines. The first indications of manganese will be the fluting at 558, and so on. Again, on account of the masking effect of the spectrum of one element upon that of another, we may sometimes have an element indicated in a star spectrum, not by the brightest band or fluting in its spectrum, but by the second or even third in brightness ; this, of course, only occurs when the darkest band falls on one of the brightest flutings of

[1] The Bakerian Lecture, delivered at the Royal Society on April 12, by J. Norman Lockyer, F.R.S. Continued from p. 35.

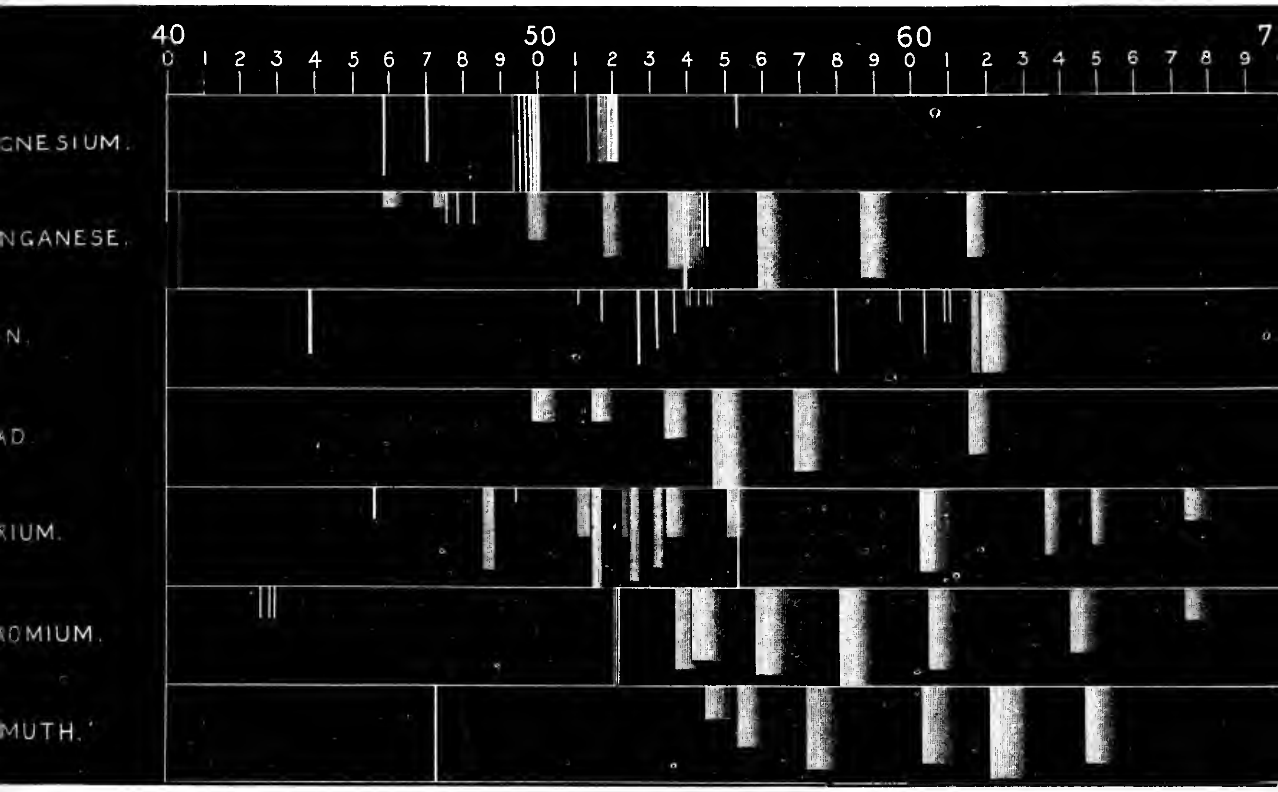

FIG. 8.—Map showing the lines, bands, and flutings seen in the spectra of the elements which are indicated in bodies of Group II. The map is intended to show also the relative intensities of the different lines, bands, and flutings, the lines, &c., seen in the lowest horizon being those seen at the lowest temperature.

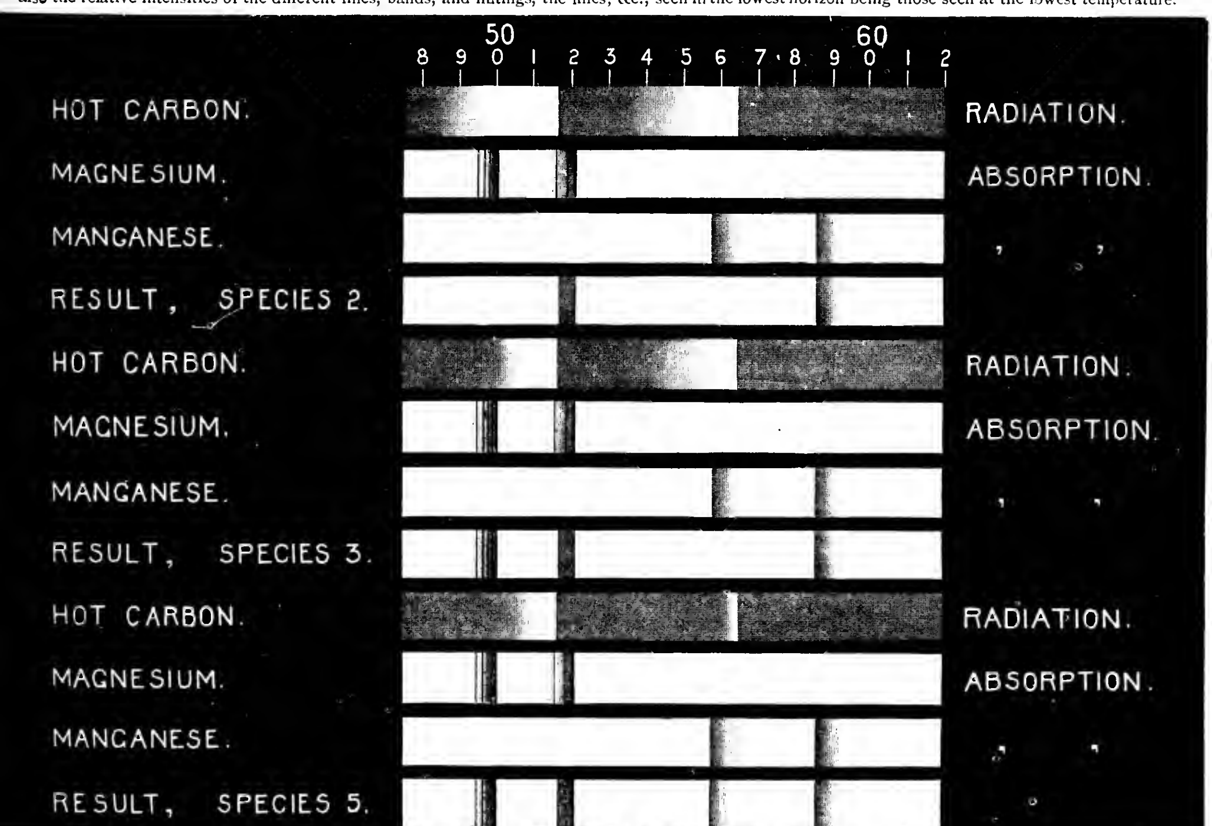

FIG. 9.—Diagram showing the effects of variations in width of the flutings of carbon upon the integrated spectra of carbon radiation, and magnesium and manganese absorption, as they occur in different species of bodies of Group II. The carbon radiation alone would give bright bands, while the absorption alone would give dark ones; but if the bright and dark bands fall in the same regions of the spectrum, the result will be enfeebled radiation, enfeebled absorption, or *nil*, according to the relative quantities of radiating and absorbing substances present. Thus, in species 2, the magnesium fluting at 500 is masked by the carbon fluting at 517, but as the quantity of carbon diminishes, it appears as an absorption band.

carbon, or upon a dark band in the spectrum of some other element. In the former case the dark band will be cancelled or masked; in the latter case the two absorptions will be added together, and form a darker band of a different shape.

The Question of Masking.

If we consider the masking effects of the bright carbon flutings upon the absorption spectrum of each of the elements which, according to the results obtained, enter into the formation of Dunér's bands, we have the following as the main results:—

Magnesium.—There are two flutings of magnesium to be considered, the brightest at 500 and the other at 5201. In the earlier stages of Dunér's stars only the fainter one at 5201 is visible, but the absence of the brightest at 500 is accounted for by the masking effect of the bright carbon fluting starting at 517. As the carbon fades, the 517 fluting narrows and the absorption of magnesium 500 becomes evident.

Manganese.—The two chief flutings of manganese are at 558 and 586, the former being the brightest fluting in the spectrum. The *second* fluting is seen in all of Dunér's stars. The first fluting, 558, however, does not appear as an absorption fluting until the radiation fluting of carbon starting at 564 has narrowed sufficiently to unmask it. It is thus easy to understand why, in some stars, there should be the second fluting of manganese without the first.

Barium.—The spectrum of barium consists of a set of flutings extending the whole length of the spectrum, and standing out on this as a background are three bright bands; the brightest band is at 515, the second is at 525, and the third, a broader band, is about 485. The *second* band is recorded as an absorption band in Dunér's stars, the apparent absence of the *first* band being due to the masking effect of the bright carbon at 517. The third band at 485 probably forms a portion of band 9. A fourth band, at 533, and the three brightest flutings at 602, 635, and 648 are also seen in α Orionis.

Lead.—The brightest fluting of lead is at 546. This first appears in species 5, as a result of increased temperature, and not on account of the removal of any previous mask. The second fluting of lead, at 568, also appears in two cases.

Chromium.—The flutings of chromium do not form portions of the ten principal bands of Dunér, but the brightest are seen in α Orionis. The brightest fluting is at 580, and this forms band I.; the second, at 557, is masked by the manganese fluting at 558, and the third at 536 is seen as line 2. The chromium triplet about 520, which is visible in the bunsen, is seen as line 3.

Bismuth.—The brightest fluting of bismuth is at 620, the second is at 571, the third at 602, and the fourth is at 646. The first is masked by the iron fluting at 615, the second is probably seen in α Orionis as band II. (570–577).

The points I consider as most firmly established are the masking effects of the bright carbon flutings and the possibility of the demonstration of the existence of some of the flutings in the spectrum by this means, if there were no other. There are two chief cases, the masking of the "nebula" fluting 500 by the bright carbon fluting with its brightest, less refrangible edge at 517, and that of the strongest fluting of Mn = Mn(1) 558, by the other with its brightest edge at 564. I have little doubt that in some quarters my anxiety not to be content to refer to the second fluting of Mn without being able to explain the absence of the first one, will be considered thrown away, as it is so easy to ascribe any non-understood and therefore "abnormal" spectrum to unknown physical laws; but when a special research had shown me that at all temperatures at which the flutings of manganese are seen at all, the one at 558 retained its supremacy, I felt myself quite justified in ascribing its absence in species 1–4 to the cause I have assigned, the more especially as the Mg fluting which is visible even in the nebula followed suit.

The Characteristics of the Various Species.

I append the following remarks and references to the number of the bodies in Dunér's catalogue, in which the specific differences come out most strongly, to the tabular statement. I also refer to some difficulties.

Sp. 1. The characteristic here is the almost cometary condition. All three bright carbon flutings generally seen in comets are visible; 474 standing out beyond the end of the dull blue continuous spectrum of the meteorites, 516 masking Mg 500, and 564 masking Mn(1) 558. The bands visible in the spectra of bodies belonging to this species will therefore be Mn(2) 586, and Mg(2) 521; band 9 will be so wide and pale that it would most likely escape detection. It is very doubtful whether any of the bodies the spectra of which have hitherto been recorded can be classed in this species, but laboratory work assuredly points to their existence; it will therefore be extremely interesting if future observations result in their discovery. It is possible, however, that No. 150 of Dunér's list belongs to this species, but the details are insufficient to say with certainty. His description is as follows:—"150. Il me parait y avoir une bande étroite dans le rouge, et une plus large dans le vert" (p. 55).

Sp. 2. Characteristics: appearance of Fe. The number of bands now visible is three—namely, 2, 3, and 7. The iron comes out as a result of the increased temperature. Mg(1) and Mn(1) are still masked by the bright carbon flutings, and there is still insufficient luminosity to make the apparent absorption band 9 dark enough to be noticed.

Sp. 3. Characteristics: appearance of Mg 500, which has previously been masked by the carbon bright fluting 517. 8 and 7 are now the darkest bands in the spectrum, 37.

Sp. 4. Characteristics: appearance of Pb(1) 546, *i.e.* band 5. This, if present in the earlier species at all, would be masked by the bright carbon at 564.

Sp. 5. Characteristics: Mn(1) is now unmasked. The bands now visible are 2, 3, 4, 5, 7, and 8, the two latter still being the widest and darkest, because they are essentially low-temperature phenomena.

Sp. 6. Characteristic: band 6, *i.e.* Ba(2), 525, is now added. The first band of Ba at 515 is masked by the bright carbon at 517. The bands now visible are 2–8, 7 and 8 still being widest and darkest. They will all be pretty wide, and they will be dark because the continuous spectrum will be feebly developed.

Sp. 7. Characteristics: appearance of band 9. This, which has been already specially referred to, has been too wide and pale to be observed in the earlier species. Its present appearance is due to the narrowing and brightening of the carbon at 474 and the brightening of the continuous spectrum, the result being a greater contrast. Bands 7 and 8 still retain their supremacy, but all the bands will be moderately wide and dark.

Sp. 8. Characteristics: all the bands 2–9 are more prominent, so that 7 and 8 have almost lost their supremacy.

Sp. 9. Characteristic: appearance of band 1, the origin of which has not yet been determined. All the bands are well seen, and are moderately wide and dark.

Sp. 10. Characteristics: appearance of band 10, and in some cases 11. These become visible on account of the brightening of the carbon B fluting and the hydrocarbon fluting at 431. The spectrum is now at its greatest beauty, and is discontinuous.

Sp. 11. Characteristics: the bands are now becoming wider, and 2 and 3 are gaining in supremacy; 7 and 8 become narrower on account of the increased temperature. 1 and 10 are only occasionally seen in this species.

Sp. 12. Characteristics: with the expansion of the continuous spectrum towards the blue, band 9 becomes very narrow, and cannot be observed with certainty. The other bands, with the exception of 7 and 8, are becoming wider and paler, while 2 and 3 still gain in supremacy.

Sp. 13. Characteristics: 9 has now entirely disappeared, 2 and 3 still retaining their supremacy.

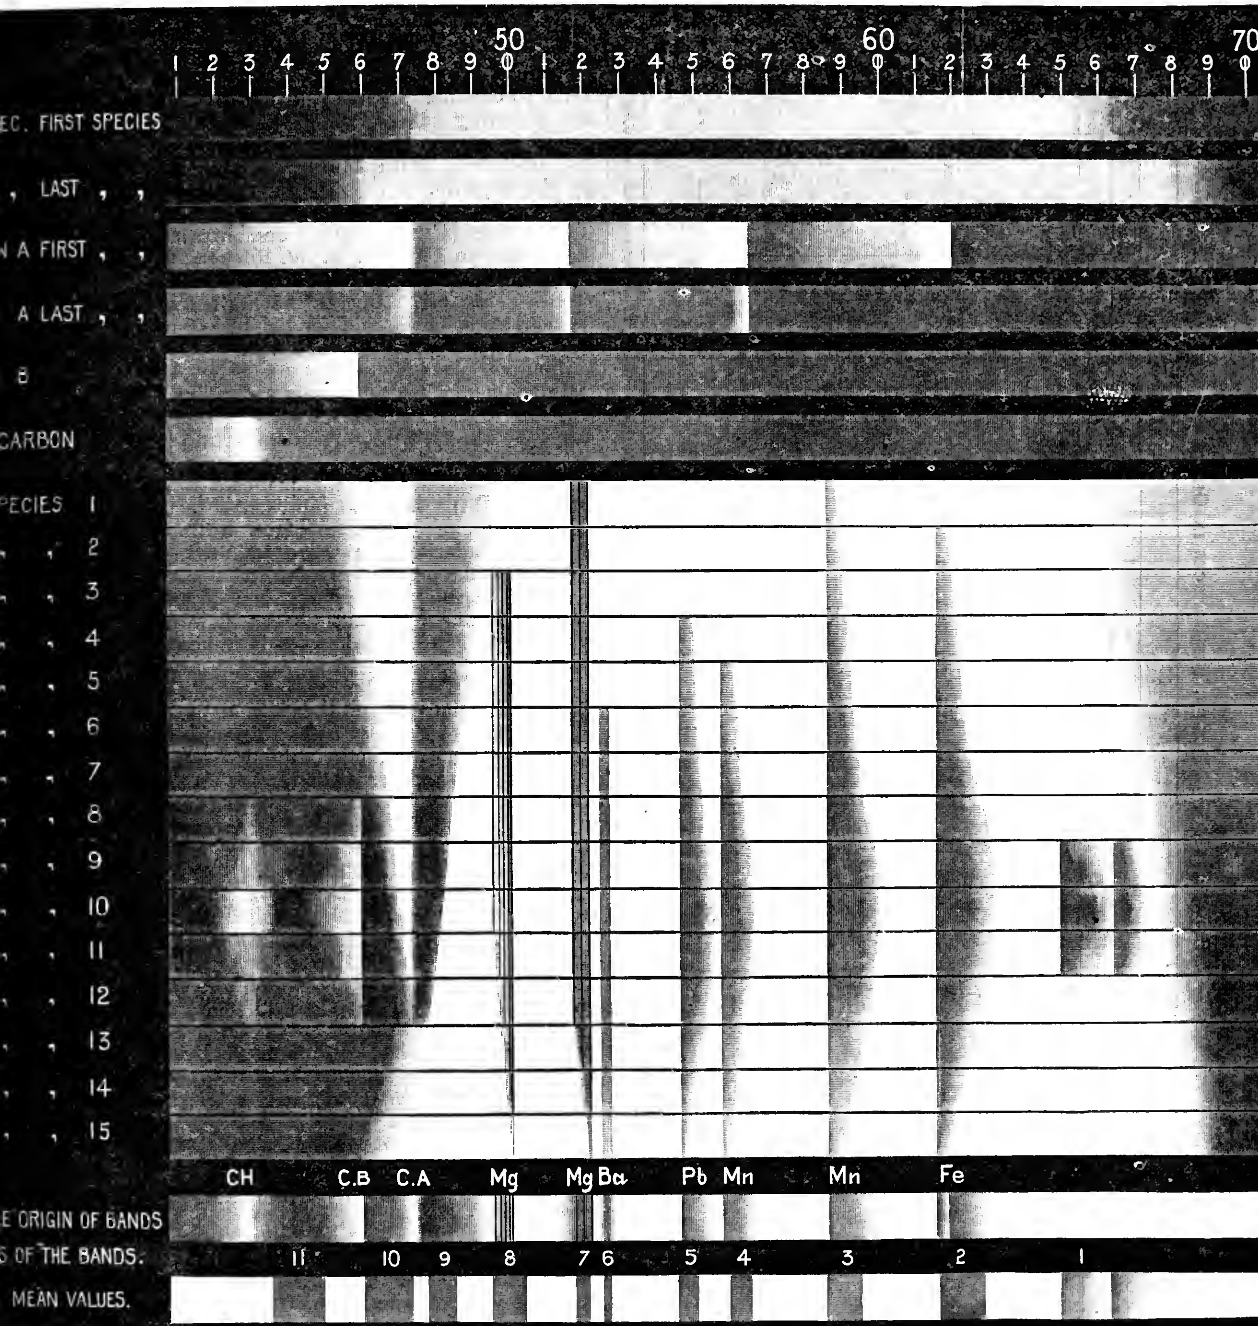

FIG. 10.—Map showing the spectra of the various species of the bodies of Group II., and the probable origin of the bands. The carbon flutings are widest in the first species, and gradually narrow until, in the last species, only a trace of 517 remains. The length of the continuous spectrum gradually increases as the carbon flutings narrow. The carbon B[1] fluting, and the hydrocarbon fluting are only seen in species 8 to 12.

Sp. 14. Characteristics: all the bands are pale and narrow; 2 and 3 will still be darkest, but the difference will not be so great as in the species preceding.

Sp. 15. Characteristics: in ordinary members of this group, 2 and 3 now alone remain visible: they are wide, but feeble, as the continuous spectrum which has been rapidly developing during the last changes is now strong.

TABLE A.—SPECIFIC DIFFERENCES IN GROUP II.

Species	Radiation flutings of carbon.					Absorption flutings.										Whether hydrogen lines.
	Hydro-carbon, 431.	Carbon B, 461.	474.	517.	564.	10.	9.	8. Mg.	7. Mg.	6. Ba.	5. Pb(1).	4. Mn(1).	3. Mn(2).	2. Fe.	1.	
1	━	━	Very wide and pale	Wide and pale	Wide and pale	━	━	If present mask'd by 517	Thin & dark	━	━	Present but mask'd by 564	Thin and pale	Absent	━	Yes
2	━	━	,,	,,	,,	━	━	,,	,,	━	━	,,	,,	Appears thin and pale	━	No

15	━	━				━	━	Gone	Gone	Gone	Gone	Gone	,,	,,	━	No

NOTE.—The lecturer here referred to tables showing the bodies of this group recorded in Dunér's Catalogue arranged in species, in accordance with the above scheme.

(*To be continued.*)

THE ROYAL SOCIETY CONVERSAZIONE.

THE first *conversazione* of the season was held on May 9, and was very numerously attended. More pains than ever seemed to have been bestowed on the arrangements, and the results entirely justified them. As the carefully prepared programme covers eighteen closely printed pages, we can only give a very summary account of the most important demonstrations and exhibits.

Following recent precedents, the meeting-room was devoted to demonstrations by means of the electric lantern, the following being given: image of electric spark, by Dr. Marcet; Mr. Poulton's teeth of Ornithorhynchus, by Dr. Hickson; Forth Bridge, by Mr. Baker; collieries, by Mr. Sopwith.

The chief exhibits in the other rooms were as follow:—

Experiments on the optical demonstration of electrical stress, shown by Prof. A. W. Rücker, F.R.S., and Mr. C. V. Boys. These experiments are similar to those devised by Dr. Kerr, the arrangements being modified so as to render them suitable for exhibition in public. Conductors of various forms are immersed in bisulphide of carbon and placed between crossed Nicol prisms. When the conductors are oppositely electrified the medium is thrown into a state of stress, and the light which had been extinguished by the analyzing prism is restored. The various forms of conductors employed are—parallel cylinders, concentric cylinders, parallel planes, a plane and cylinder, and plates bent so as to represent a section of a Leyden jar. Many of the phenomena exhibited by crystals in plane polarized light are imitated—*e.g.* the black cross and the production of colours similar to those in Newton's rings. A bright field can be maintained by the introduction of a plate of selenite between the Nicols, in which case the electrical stress is indicated by change of colour.

Large electrical influence machine, exhibited by Mr. James Wimshurst. It has twelve disks of 2 feet 6 inches in diameter; each disk carries sixteen metal sectors. The machine is self-exciting in any condition of atmosphere. It shows large and perfect brush discharge at its terminals. With Leyden jars it will give sparks $13\frac{3}{8}$ inches in length.

Photographs of flashes of lightning, exhibited by the Royal Meteorological Society.

Radio-micrometer, exhibited by Mr. C. V. Boys. This is probably the most delicate instrument for measuring radiant heat yet made. It consists of a circuit made of antimony, bismuth, and copper hung by an exceedingly fine fibre of quartz in a strong magnetic field. A scale model of the circuit, twenty times the size or 8000 times the weight, shows the construction of the suspended part of the instrument. The fibre, if magnified to the same extent, would still be finer than spun glass. The proportions of the several parts are those which have been found by calculation (confirmed by experiment) to give the greatest possible delicacy.

Experiments with soap-bubbles, also shown by Mr. Boys. These experiments are arranged to show chiefly the power of an air-film to prevent two bubbles from coming into real contact. Thus, among other experiments, the outer of two bubbles may be pulled out until it squeezes the inner one into a long oval, but no real contact takes place. An inner bubble filled with gas will carry up an outer one to which are attached a wire ring and other things without really touching it at all. A bubble will roll down a spiral groove, also made of soap-film, or jump one or two steps at a time down a spiral staircase made of soap-film, without touching the spiral film or being injured in the least. Some of the experiments show the effects of diffusion, of vibration, of magnetism, or of electricity upon bubbles or groups of bubbles.

Maps and diagrams illustrative of the recent work of the Geological Survey in the North-West Highlands, exhibited by the Director-General of H.M. Geological

Survey. The maps, on the scale of 6 inches to a mile, show the remarkable geological structure of the west of Sutherland. A series of enormous dislocations runs in a southerly direction from the mouth of Loch Eriboll to Skye. By these disruptions the most ancient rocks have been torn up from great depths, and have been launched bodily westwards, sometimes for several miles. The displaced masses now rest upon other shifted portions or upon wholly undisturbed rocks, and the extraordinary structure is presented of vertical and highly inclined strata, with their unconformable junctions standing upon gently inclined and much younger rocks. The diagrams are taken across some of the more typical parts of the district, and give some idea of the physical problems presented by this region, which undoubtedly exhibits the most complicated geological structure in the British Isles.

Sections and specimens illustrating the recent borings in the Delta of the Nile, exhibited by Prof. J. W. Judd, F.R.S., on behalf of the Delta Committee. The whole of the samples obtained in these borings have now reached the Royal Society, and the examination of the materials reveals some facts of great geological interest. The alterations and mixtures of blown sand and Nile alluvium were found to continue down to the depth of 121 feet from the surface and 95 feet below the level of the Mediterranean. At that depth a remarkable change in the deposits took place, and beds of gravel containing both pebbles and subangular fragments of quartzite, chert, compact limestone, with some metamorphic and igneous rocks, were found; and similar beds occur at intervals down to the greatest depth reached. Up to the present time no contemporaneous organic remains have been found in these deposits.

Fossil plants from Ardtun in Mull, exhibited by Mr. J. Starkie Gardner. These plants are from a small patch of limestone beneath the gravels and silts of an old river course sealed up in the great trap flows of Western Scotland. The limestone is rather below the leaf-bed found at Ardtun by the Duke of Argyll, and directly overhangs the sea, the cliffs beneath being columnar and worn into caverns. The plants were until recently believed to be Miocene, but are now recognized to be very low down in the Eocene—*vide* recent writings of Sir W. Dawson and the Marquis de Saporta. The same plants ranged over Greenland and North America during the Tertiary, perhaps not synchronously, and an allied flora seems to exist at the present day in China and Japan.

Photographs illustrating experiments in mountain-building, exhibited by Mr. Henry M. Cadell, H.M. Geological Survey of Scotland. These have already been referred to in NATURE.

Set of thermometers specially constructed by Casella for use by Mr. Symons in determining the present temperature of the mineral springs in the Pyrenees, exhibited by Mr. G. J. Symons, F.R.S.; and Immisch's avitreous thermometer, constructed for the above investigation. This thermometer is absolutely perfect, its verification at Kew, before and after its use in the Pyrenees, being 0°·0 at all points from 50° to 130°.

An apparatus for determining the hardness of metals or other substances, exhibited by Mr. Thomas Turner.

Robertson's writing telegraph, exhibited by Mr. John M. Richards.

A Coulomb-meter, exhibited by Prof. George Forbes, F.R.S. This consists essentially of a conductor of iron wire in the form of a spiral, or a double ring with cross wires. Above the conductor a set of vanes is pivoted. This consists of a circular disk of mica with a hole in the centre in which is fixed a paper cone carrying at its apex a pinion with a concentric ruby cup. Round the circumference of the mica disk eight small cylinders of pith are fixed at equal distances, and eight vanes inclined at 45° to the mica disk are attached to the pith cylinders, these vanes being made of the thinnest mica. This set of vanes is supported by the ruby cup resting on a steel point fixed to the base of the instrument. The pinion engages with the first wheel of a train of wheelwork actuating the indexes, which show upon dials the number of revolutions made by the vanes. The action of the instrument is very simple. The electric current passing through the iron conductor creates heat, which sets up a convection current in the air, and this causes the vanes to rotate about the vertical axis and drive the clockwork. The number of revolutions indicated on the dials is, through a considerable range of currents, an exact indication of the number of coulombs or ampere-hours which have passedth rough the conductor. The friction of the ruby cup on the pivot determines the smallest current which can be accurately measured, and the friction of the clockwork is barely perceptible. The resistance of a meter to read from 1 ampere upwards is 0·02 ohm.

Electrical translucent balloon for flashing signals by night, invented and exhibited by Mr. Eric Stuart Bruce.

The new iridio-platinum incandescent gas-burner (Lewis and Sellon's patents), exhibited by Messrs. Johnson, Matthey, and Co.

Apparatus for measuring the changes produced by magnetization in the dimensions of rods and rings of iron and other metals, exhibited by Mr. Shelford Bidwell, F.R.S. The instrument exhibited is capable of measuring changes of length to a millionth of a millimetre or a twenty-five-millionth of an inch. An *iron* rod when magnetized becomes (as is well known) at first slightly lengthened. But if the magnetizing force is sufficiently increased it again contracts, and ultimately becomes actually shorter than when unmagnetized. A *cobalt* rod contracts under magnetization, reaching a minimum length in a field of about 500 C.G.S. units, beyond which point it becomes longer. A *nickel* rod also contracts; the limit of its contraction not having been reached with the greatest magnetizing forces yet used. *Bismuth* is slightly elongated in intense fields. (See Proc. Roy. Soc., vol. xliii., 1888, p. 406.)

Experiments illustrating low-temperature spectra, in connection with the spectra of meteorites, shown by Mr. J. Norman Lockyer, F.R.S.

Skeleton of an Akka, a Negro tribe from Central Africa, the smallest known race of men. (Height exactly 4 feet.) Sent by Dr. Emin Pasha for the British Museum, and exhibited by Prof. Flower, C.B., F.R.S.

Charts showing lines of equal values of the magnetic elements (epoch 1880)—declination or variation, inclination or dip, horizontal force (British units), vertical force (British units)—exhibited by Staff-Commander E. W. Creak, R.N., F.R.S. From the original charts at the Admiralty, compiled by Staff-Commander E. W. Creak, and prepared in their present form for the "Report on the Magnetical Results obtained in H.M.S. *Challenger*," in the concluding volume of the "Voyage of H.M.S. *Challenger*." The small maps show—(1) The track of H.M.S. *Challenger* where magnetic observations were made. (2) The approximate distribution of the secular change in the declination or variation (epoch 1840–80).

Photographs of the polar axis of a 5-foot telescope, December 1887, January 1888, exhibited by Mr. A. A. Common, F.R.S.

Sir William Thomson's models of foam or froth consisting of equal bubbles, exhibited by Prof. G. H. Darwin, F.R.S. Each bubble is a curvilinear fourteen-faced space. If a single bubble be dissected from the mass, it is found to be derived from the regular octahedron (two square pyramids base to base) by truncating the six solid angles. Thus the eight faces of the octahedron give rise to eight curvilinear hexagons, and the six solid angles to six solid curvilinear squares. In the foam three films meet at 120 at each edge, and of the three which meet two are hexagons and one is a square. (See *Phil. Mag.*, vol. xxiv., 1887, p. 503.)

Model of maximum pressure anemometer, designed by Mr. Whipple, Superintendent of Kew Observatory, exhibited by the Kew Committee. In this instrument eight small metal disks, each of 0·01 foot in area, are supported vertically against the wind by levers weighted in accordance with the various pressures of the wind on Beaufort's, or some other accepted scale of force. A vane keeps their surfaces normal to the wind's direction. By their displacement the maximum wind pressure during any desired period is registered. The large perforated disk against which they are pressed serves the purpose of removing the indicating disks beyond the action of the eddies of the wind playing round the edges of the plate.

Specimens of gold showing the effect of small quantities of impurity on the fracture of the metal, exhibited by Mr. W. C. Roberts-Austen, F.R.S.

Miners' electric safety-lamps, exhibited by the Schanschieff Electric Light and Power Company. (1) A three-cell lamp capable of giving 1½ candle-power for 9 hours. Each cell contains 5 fluid ounces of solution, and consumes ⅝ pound of zinc in 48 hours. The light is more than four times more powerful than that of the Clanny oil lamp, and its working cost is ⅝*d.* per shift of 9 hours, or 3¾*d.* per week. The weight when fully charged is about 3¼ pounds. The elements consist of carbon and zinc, and the excitant is a mercurial solution of Mr. Schanschieff's invention. (2 and 3) Four-cell batteries, one round and one square. Each cell contains 5 fluid ounces of solution, and at a cost of 1*d.* furnishes a light of nearly 2 candle-power for 9 hours. The weight when fully charged is 4½ pounds. (4) A four-cell reversible battery, *i.e.* put in or out of action by reversing it. The charge consists of 24 ounces of solution, and giving a light of 2 candle-power will burn from 10 to 12 hours at a cost of 1*d.* The batteries can be used for many purposes other than mining-lamps, viz. for microscopical purposes, house-lighting, photography, diving, railway-lighting, gun-firing, gas-works, &c.

THE ZOOLOGICAL SOCIETY OF AMSTERDAM.

THE celebration of the jubilee of the Zoological Society of Amsterdam (*Natura Artis Magistra*), on Tuesday and Wednesday, May 1 and 2, passed off with great *éclat*. Dr. Westerman, who has been Director of the Gardens for more than fifty years, may well be congratulated on the success of the jubilee *fêtes;* and the vigour with which he spoke at the banquet on May 1, and again at the distribution of honours on Wednesday, shows that his eighty years sit lightly upon him. One of the most interesting features of the jubilee commemoration was the performance of a festival cantata, specially composed for the occasion by Mr. De Langa, and this had to be repeated on Thursday for the benefit of half the members of the Society, for whose accommodation the enormous concert-room proved insufficient on the opening day. All the streets in the vicinity of the Zoological Gardens were gaily decorated with flags, and the rooms of the Society were ornamented in the day-time by a mass of gorgeous flowers and at night with brilliant illuminations. After the reception of the guests by the Committee on Tuesday morning, an adjournment was made to the King's Saloon, which was densely crowded, to hear an address from Prof. Stockvis. Luncheon followed, and then the cantata was given in the concert hall, and in the afternoon the new Ethnographical Museum was formally opened. The excellent way in which the collections had been arranged was generally remarked, and the Curator, Mr. Pleyte, was warmly congratulated. The public spirit which characterizes modern Amsterdam will doubtless soon cause this new Museum to become famous, as there is a vast field for research among the Netherland possessions in the East Indies. At the banquet in the evening, covers were laid for nearly 200 persons, and after the usual toasts, the health of the Queen of England was drunk by the assembled company with the greatest enthusiasm, and was responded to by Mr. Bowdler Sharpe, of the British Museum, who spoke in English, and took the opportunity of thanking the Dutch nation for the hospitality which he and his countrymen always received from the Netherlanders, to which he could testify from an experience of over twenty years. Speeches were also given by the Ministers of Finance and of the Interior, the Burgomaster of Amsterdam, and others; and the company then adjourned to witness a torchlight procession of students, who sent a deputation of their Senate to congratulate the venerable Director and the Committee of the Society. The young President of the Students' Senate, Mr. Van Schevichaven, made a most eloquent address, and was enthusiastically received. On Wednesday, May 2, a special reception of the Committee was held to confer diplomas on the new honorary members, and Prof. Hubrecht, of Utrecht, Dr. Jentink, the Director of the Royal Museum of Natural History at Leyden, and Mr. Büttikofer, of the same Museum, were the first recipients; being followed by Mr. A. D. Bartlett, the Superintendent of our Zoological Gardens in the Regent's Park, and Mr. Bowdler Sharpe. Amongst those who were unable to be present, but to whom the honorary membership of the Society was given, were Prof. Flowers, Dr. A. B. Meyer, &c. The large bronze medal of the Society was conferred on Mr. Charles Jamrach and Mr. G. A. Frank for services rendered in the formation of zoological collections, as well as on several other well-known zoologists. Mr. Jansen, the Librarian of the Society, and Mr. F. E. Blaauw, the Secretary, also received medals and diplomas. The latter gentleman has a large private menagerie, and is an enthusiastic supporter of the Society. Simultaneously with the festival celebration, the Society has issued a jubilee number of its *Bijdragen tot de Dierkunde*, containing several important memoirs, of which the following is a list:—(1) The opening address of Prof. Stockvis. (2) Mr. Maitland's review of the Society and its work, with a plan of the Gardens. (3) An account of the aquarium with 2 plates, by Dr. C. Kerbert, the Curator. (4) A list of all the animals which have lived in the Gardens from 1838 to 1888 by Mr. K. N. Swierstra. (5) A list of the birds of the Netherlands, by Mr. H. Koller, with an enumeration of the specimens in the Society's collection. (6) Description of a new species of *Proechidna* (*P. villosissima*) and an account of *Canis jubata*, by Prof. Max Weber: this article is illustrated by 2 plates. (7) A list of the *Macrolepidoptera* of Holland, by Dr. J. T. Oudemans. The Gardens of the Society seemed to be in flourishing condition, and the collections of Cranes and Antelopes were as remarkable as ever.

NOTES.

THE ceremony at Utrecht on May 28 to celebrate the seventieth birthday of Prof. Donders, and his consequent retirement from his Professorship, will comprise a formal presentation, at 1.30 p.m., of the sum collected, together with the roll of subscribers, and a public dinner at 5.30 p.m. After the ceremony of presentation the Professor will name the scientific purpose to which he proposes that the fund shall be applied. The complete list of subscribers from this country is to be seen in our advertising columns on page xviii. Any subscriber may verify the amount of his subscription by applying to Mr. Brailey, 11 Old Burlington Street, where the audited list may be seen. The total amount collected here is £280 11*s.* 10*d.* Prof. Humphry, Dr. Hughlings

Jackson, Mr. Hutchinson, and Mr. Brailey have been invited to attend as delegates to represent the subscribers, and it is hoped that many others may be able to attend, and by their presence do honour to Prof. Donders.

THE meeting of the National Academy of Sciences, lately held at Washington, seems to have been remarkably successful. According to *Science*, the most important papers read at the meeting were, the orbits of aërolites, by Prof. H. A. Newton; preliminary notice of the object, methods, and results of a systematic study of the action of definitely related chemical compounds upon animals, by Profs. Wolcott Gibbs and Hobart Amory Hare; and report of progress in spectrum photography, and note on the spectrum of carbon and its existence in the sun, by Prof. H. A. Rowland. Prof. Newton, in his paper, submitted the two following propositions:—(1) The meteorites which we have in our collections, and which have been seen to fall, were originally (as a class, and with a very small number of exceptions) moving about the sun in orbits that had inclinations to the ecliptic of less than 90°; that is, their motions in the solar system were direct and not retrograde. (2) The reason why we have only this class of stones in our collections is not a reason wholly, or even mainly, dependent on the habits of men; nor on the times when men are out of doors; nor on the places where men live; nor on any other principle of selection acting at or after the arrival of the stones at the ground. Either the stones which are moving across the earth's orbit in the solar system move in general in direct orbits, or else, for some reason, the stones which have retrograde orbits do not in general come through the air to the ground in solid form.

Two gold medals were presented at this meeting: the Lawrence Smith gold medal to Prof. Newton for his study of meteors; the Henry Draper gold medal to Prof. E. C. Pickering for researches in stellar photography. On the evening on which these presentations were made the following obituary memoirs were read: on the late Prof. Henry Draper, of New York, by Prof. G. F. Barker, of the University of Pennsylvania; on Prof. Watson, of the University of Michigan, by Prof. Comstock; on Capt. J. B. Eady, by Mr. W. Sellers, of Philadelphia.

WE are glad to see that the National Association for the Promotion of Technical Education is hard at work, and that it is likely to do excellent service to the cause it supports. In reply to circulars sent out in August and September 1887 a good deal of information has been provided from various industrial centres, which it is hoped may form the basis of a fairly complete report as to what is being done for technical education in the United Kingdom at the present time. Meetings have been held in a good many towns, and in some cases branches or corresponding Associations have been established. The Association is also issuing a series of publications, each consisting of a page or two, and presenting in a clear, popular style some important aspect of the subject. Some of these papers are sold at sixpence, others at a shilling, per hundred, and we may hope that large numbers of them will be widely circulated. In a series of more elaborate publications the Association has included the admirable address delivered by Prof. Huxley at a meeting held in the Town Hall, Manchester, on November 29 last.

COLONEL TURNER'S Report on the present state of the borings in the Delta of the Nile has been received at the Royal Society. The total result of the whole operations is to prove that no rock exists at a depth of 345 feet at Zagazig; at a depth of 45 feet at Kasr-el-Nil; at 84 feet at Kafr-Zayat; or at 73 feet at Tantah.

THE May number of the Kew Bulletin contains an interesting paper, giving an account of the attempts that have been made to introduce ipecacuanha into India, and the successful cultivation of the plant in the Straits Settlement. There are also valuable papers on Brazilian gum arabic, Trinidad coffee, patchouli, Cochin China vine, Madagascar ebony, and Shantung cabbage.

ABOUT a year ago the Botanical Department, Jamaica, began to issue Bulletins. Six numbers have been sent to us, and each of them contains some contribution or contributions worthy of attention. The compilers very wisely keep local industrial needs steadily in view.

IN a Report on the province of Florence, just laid before Parliament, Mr. Colnaghi, British Consul-General, says that meteorological stations, both public and private, are now established at the following places in the province:—Florence (5), Fiesole, Vallombrosa, Prato, Pistoia, Scandicci, Empoli, Fiorenzuola, Castaletti, and thermo-pluviometrical stations at S. Miniato, Mercatale (in Rocca San Casciano), Pontassieve, and Barberino di Mugello. Amongst the more important of these, he mentions the Observatory of the Royal Museum of Physical Science, that attached to the medical section of the Reale Istituto di Studi Superiori, chiefly devoted to the study of the variations of the atmosphere, and the Osservatorio Ximeniano, which is, at the same time, astronomical, meteorological, and seismical, and is under the direction of the Fathers of the Scuole Pie. For many years, he adds, experiments have been made by Prof. F. Meucci, of the Observatory of the Royal Museum of Physical Sciences, for the purpose of ascertaining the correlation of meteorological phenomena with the productiveness of the soil, and a series of Reports have been published. In 1880 the Royal Tuscan Society of Horticulture established, in its experimental garden at Florence, a Meteorological and Physical Observatory, by means of which the relation existing between the vegetation of plants and the meteoric phenomena can be studied. The Royal Astronomical Observatory of Florence is established at Arcetri, and is under the direction of Prof. Tempel.

VOLUME X. of the *Repertorium für Meteorologie*, issued by the Imperial Academy of Sciences of St. Petersburg, and edited by Dr. H. Wild, contains, among other interesting discussions, one upon the anticyclones in Europe, by Dr. P. Brounow. He has investigated by means of synoptic charts the barometrical maxima which passed over Europe in the years 1876-79, with especial reference to their movements and their causes—questions which up to the present time have received but little attention, although they are intimately connected with the movements of cyclonic areas. The number of the maxima whose paths are drawn on the charts, are most frequent in August, and least so in July and March; and, generally speaking, their motion is towards east-south-east, while their motion towards the north-westerly portion of the compass is very rare. Among the chief results of his inquiry may be mentioned that the prevalent movement of the maxima does not coincide with that of the barometric minima, but deviates from it by an angle of $67\frac{1}{2}°$. There appears to be no important difference in the mean velocity of their motion in different seasons, and although they move more slowly than the depressions, the difference of velocity is not so great as is generally assumed. Their origin is attributed to two principal causes: (1) terrestrial radiation, and (2) the proximity of two or more barometric minima. The work is accompanied by sixteen charts, from which the author concludes that the maxima advance generally in the direction in which the lowest temperature exists, and that the lower the temperature sinks the quicker the centre of the maximum advances, without reference to the season of the year.

AN important addition to the chemistry of the element tellurium is contributed by MM. Berthelot and Fabre to the May number of the *Annales de Chimie et de Physique*. They find that this metalloid, one of the most remarkable links between the non-metals and true metals, is capable of existing in three distinct allotropic forms. Besides the well-known crystalline form, exhibiting so strongly the metallic lustre, the form in which one always obtains it by volatilization in an atmosphere of hydrogen, it may be obtained by precipitation in two very different amorphous varieties. One of these is the product of the reduction of tellurous or telluric acids by sulphurous acid, and the other is formed when solutions of the alkaline tellurides are exposed to the oxidizing action of the air. Both these amorphous varieties are dark-coloured powders very liable to oxidation in the air, and only to be obtained pure by working in an atmosphere of nitrogen. The physical difference between the two is most strikingly shown, however, by their thermo-chemical behaviour. All three varieties are rapidly dissolved by a mixture of bromine and bromine water, and during the reaction in case of both the crystalline variety and the amorphous form obtained by oxidation of tellurides 33·4 heat units are evolved, while in case of amorphous tellurium derived by reduction with sulphurous acid only 21·3 units are disengaged. There was no mistake as to the purity of this latter kind, for it was completely converted to crystals on sublimation in a current of hydrogen. Hence it follows that one of the precipitated forms of tellurium corresponds to the crystalline state, and the other possesses an entirely different physical nature. It is curious, moreover, that all three modifications have the same specific heat. These interesting facts render the analogy between sulphur, selenium, and tellurium still more complete. MM. Berthelot and Fabre have also discovered a new and far superior method of preparing telluretted hydrogen. They first pass vapour of tellurium over metallic magnesium heated in a current of hydrogen, and afterwards treat the magnesium telluride thus formed with dilute hydrochloric acid in an apparatus previously filled with an atmosphere of nitrogen. The telluretted hydrogen, which is obtained in a very pure state by this new method, is very unstable, decomposing on standing in a tube over mercury even in the dark, coating the interior with tellurium and leaving its own volume of hydrogen. Decomposition is immediate in contact with moist air. In conclusion, the French chemists show that the combination of the elements of the sulphur group with hydrogen is attended with a beautifully graduated series of thermal changes, from water with heat of formation + 59 units down to telluretted hydrogen with − 35 units.

Science gives an interesting account of a magnificent ethnographical collection from Alaska, brought together by Lieut. Emmon. It has been presented to the American Museum of Natural History in New York, and forms a valuable supplement to the Powell collection from British Columbia, in the same Museum. While the latter includes principally specimens of Haida and Tsimpshian origin, the objects in the new collection come from the territory of the Tlingit, in whose country Lieut. Emmon spent more than five years. The collection includes a large number of masks. They are especially valuable, as Lieut. Emmon took great pains to ascertain the meaning of the masks, which thus became a rich source of information for the student of ethnology. A comparison of these masks with others collected on Vancouver Island and in Dean Inlet shows that the style of North-West American art, although uniform in general outlines, has its specific character in various localities. The imitation of animal forms is much closer here than in the southern regions, where the forms are more conventional, certain attributes of the animal alone being added to human figures. Another and a very interesting peculiarity of these masks is to be found in the figures of animals attached to the faces. The Eskimo tribes of Southern Alaska carve their masks in the same fashion, numerous attachments belonging to each. This is another proof of the influence of Indian art upon that of the Eskimo. The figures attached to the faces refer, as a rule, to certain myths; and the like is true of the Eskimo masks and their characteristic wings and figures. A considerable number of masks show deep hollow eyes and sunken cheeks. They represent the heads of dead men. Masks with thick lips and beards, and eyebrows made of otter skin, represent the fabulous Kushtaka, the otter people, of which many tales and traditions are told. Another remarkable mask is that of the mosquito. This is of special interest, as the mosquito is among the southern tribes the genius of the cannibal; and as cannibalistic ceremonies are not known to be practised by the Tlingit, it may be assumed that the myth referring to the mosquito is found in a somewhat altered form among the Tlingit.

We learn from *Science* that a Bill providing for the establishment of a zoological park in Washington has been introduced into the United States Senate. The Bill creates a Commission, which is directed to secure one hundred acres of land bordering on Rock Creek, about one mile from the city, to prepare the grounds and erect suitable buildings upon it. The park is then to be transferred to the regents of the Smithsonian Institution for their future custody and care. The site indicated is one of the most beautiful in the District of Columbia. It is composed of rolling ground, with the beautiful Rock Creek flowing through it, and it is adjacent to Woodley Park, one of the most charming of the recent additions to Washington. A street-railway to it is already projected.

The United States Bureau of Education has issued an elaborate report of the proceedings of the Department of Superintendence of the National Educational Association at its meeting at Washington from March 15 to 17, 1887. The volume includes addresses and papers by some of the most eminent American authorities on questions relating to education.

The people of Cleveland, where the American Association for the Advancement of Science will meet in August, have already begun to prepare for the meeting, which is expected to mark an epoch in the history of the city. At a recent meeting of citizens, summoned for the purpose of appointing various local committees, an interesting address on the history of the Association and its objects was delivered by Prof. F. W. Putnam, the Peabody Professor of American Archæology and Ethnology in the University of Harvard, and Permanent Secretary of the Association since 1873.

According to the *Colonies and India*, the Government of South Australia have issued Part 8 of a work on "The Forest Flora of South Australia," which is said to be the best illustrated publication ever issued in the colony. Mr. Brown, Conservator of Forests, under whose direction the book is brought out, supplies the letterpress descriptions of the plants pictorially represented.

The American publishers, Messrs. D. C. Heath and Co., have in the press a book of "Chemical Problems," by Drs. Grabfield and Burns, of the Massachusetts Institute of Technology.

A fourth edition of Prof. G. Henslow's "Botany for Beginners" (Stanford) has just been issued. In this little book Prof. Henslow provides a short course of elementary instruction in practical botany, for junior classes and children.

At the anniversary meeting of the Hertfordshire Natural History Society, held on February 21 last, Mr. F. Maule Campbell, the President, delivered an interesting address on the means of protection possessed by plants. This address is printed in the Transactions of the Society, and has now been issued separately.

The London Geological Field Class, under the direction of Prof. H. G. Seeley, begins the summer excursions on Whit Monday, May 21, and will continue them on Saturday afternoons thereafter up to July 14. The following are among some of the places which will be visited: Leatherhead and Boxhill, to examine the gorge of the Mole in chalk; Maidstone and the vicinity, for gravels; Woolwich and Reading beds, chalk gault, and lower greensand; Erith and Crayford, for river gravels; Grays (in Essex), Northfleet, and Oxsted, for studies in chalk; and other places besides. Intending students should apply for tickets at once, as only a limited number are issued. Application forms may be had from Mr. W. P. Collins, 157 Great Portland Street.

THE additions to the Zoological Society's Gardens during the past week include a Blue and Yellow Macaw (*Ara ararauna*), from South America, presented by Mrs. Warrand; two White Ibis (*Eudocimus albus*), from South America, deposited; two Black-backed Geese (*Sarcidiornis melanonota* ♂ ♀), from India, purchased; a Puma (*Felis concolor*), two Long-fronted Gerbilles (*Gerbillus longifrons*), a Hog Deer (*Cervus porcinus*), a Sambur Deer (*Cervus aristotelis* ♂), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *MAY* 20-26.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 20

Sun rises, 4h. 2m.; souths, 11h. 56m. 21·0s.; sets, 19h. 50m.: right asc. on meridian, 3h. 50·6m.; decl. 20° 8′ N. Sidereal Time at Sunset, 11h. 45m.

Moon (Full on May 25, 14h.) rises, 13h. 0m.; souths, 19h. 49m.; sets, 2h. 23m.*: right asc. on meridian, 11h. 44·2m.; decl. 6° 3′ N.

GEOGRAPHICAL NOTES.

AT Monday's meeting of the Royal Geographical Society Lieut. F. E. Younghusband gave an account of his journey across Central Asia, from Manchuria and Peking to Kashmir and the Mustagh Pass. This is the most important paper which has been read at the Society during the present session, and the journey one of the most remarkable ever made, considering its length, the time taken—April to November, 1887—and the novelty and value of the results. We have only space to refer briefly to Lieut. Younghusband's observations on the Mustagh Pass, which he has been the first European to cross. He crossed the Gobi Desert to Hami by a route lying between those of Marco Polo and Mr. Ney Elias. His observations in the Gobi are of much interest. The clearness and dryness of the atmosphere were remarkable. Everything became parched up, and so charged with electricity that a sheepskin coat or blanket, on being opened out, would give out a loud crackling noise, accompanied by a sheet of fire. At the western end of the Hurku Hills, beyond the Galpin Gobi—the most sterile part of the whole Gobi—is a most remarkable range of sand-hills. It is about 40 miles in length, and is composed of bare sand, without a vestige of vegetation of any sort on it, and in places it is as much as 900 feet in height, rising abruptly out of a gravel plain. With the dark outline of the southern hills as a background, this white, fantastically-shaped sand-range presents a very striking appearance. It must have been formed by the action of the wind, for to the westward of this range is an immense sandy tract, and it is evident that the wind has driven the sand from this up into the hollow between the Hurku Hills and the range to the south, thus forming these remarkable sand-hills. It was near this region that traces of the wild camel were met with, and both wild asses and wild horses seen. As far as Hami the country continues to be mainly desert. From Hami, Lieut. Younghusband went on to Yarkand, and by the Yarkand River to the Karakorum Range, which he meant to cross by the Mustagh Pass. The difficulties, owing to the enormous glaciers, the rugged nature of the mountains, and great height of the pass, were very great for Mr. Younghusband, his men, and his ponies. The glaciers here are of enormous size, and Mr. Younghusband has added considerably to the information obtained by Colonel Godwin-Austen, who surveyed the region to the south of the pass twenty-six years ago. "The appearance of these mountains," Lieut. Younghusband stated, "is extremely bold and rugged as they rise in a succession of needle peaks like hundreds of Matterhorns collected together; but the Matterhorn, Mont Blanc, and all the Swiss mountains would have been two or three thousand feet below me, while these mountains rose up in solemn grandeur thousands of feet above me. Not a living thing was seen, and not a sound was heard; all was snow and ice and rocky precipices; while these mountains are far too grand to support anything so insignificant as trees or vegetation of any sort. They stand bold and solitary in their glory, and only permit man to come amongst them for a few months in the year, that he may admire their magnificence and go and tell it to his comrades in the world beneath." After some extremely difficult prospecting, Lieut. Younghusband made up his mind to cross the old and long-abandoned Mustagh Pass, instead of the new one. "Next morning," he stated, "while it was yet dark, we started for the pass, leaving everything behind, except a roll of bedding for myself, a sheepskin coat for each man, a few dry provisions, and a large tea-kettle. The ascent to the pass was quite gentle, but led over deep snow in which we sank knee-deep at every step. We were now about 19,000 feet above the sea-level, and quickly became exhausted. In fact, as we got near the summit, we could only advance a dozen or twenty steps at a time, and we would then lean over on our alpenstocks, and gasp and pant away as if we had been running up a steep hill at a great pace. But it was not till midday that we reached the summit, and then on looking about for a way down we could see none. Huge blocks of ice had fallen from the mountains which overhang the pass, and had blocked up the path by which travellers used formerly to descend from it, and the only possible way now of getting to the bottom was by crossing an icy slope to a cliff, which was too steep for a particle of snow to lodge on it, even in that region of ice and snow. From this we should have to descend on to some more icy slopes which could be seen below. . . . We had first to cross the icy slope; it was of smooth ice and very steep, and about thirty yards below us it ended abruptly, and we could see nothing over the edge for many hundreds of feet. As Wali hewed the steps we advanced step by step after him, leaning back against the slope, all the time facing the precipice, and knowing that if we slipped (and the ice was very slippery, for the sun was just powerful enough to melt the surface of it), we should roll down the icy slope and over the precipice into eternity. After a time we reached *terra firma* in the shape of a projecting piece of rock, and from here began the descent of the cliff. We had to let ourselves down from any little ledge, taking every step with the greatest possible care, as the rock was not always sound; and once a shout came from above, and a huge rock, which had been dislodged, came crashing past me and as nearly as possible hit two of the men who had already got some way down. At the bottom of the cliff we came to another steep ice-slope." After eighteen hours of this task the party were glad to lie down for a few hours' rest. At daybreak next morning they were on their legs again, and after a few hours' travelling emerged on to the great Baltoro Glacier, which was explored by Colonel Godwin-Austen in 1862, when making the Kashmir survey. They travelled all that day, and for two days more, till they reached Askoli, a little village on the Braldo River, surrounded by trees and cultivated lands.

LIEUT. YOUNGHUSBAND remarked as follows on the Altai Mountains:—"These mountains are perfectly barren, the upper portion composed of bare rock and the lower of long gravel slopes formed of the debris of the rocks above. In such an extremely dry climate, exposed to the icy cold winds of winter and the fierce rays of the summer sun, and unprotected by one atom of soil, the rocks here, as also in every other part of the Gobi, crumble away to a remarkable extent, and there being no rainfall sufficient to wash away the debris, the lower features of the range gradually get covered with a mass of debris falling from the upper portions, and in the course of time a uniform slope is created, often 30 or 40 miles in length, and it is only for a few hundred feet at the top that the original jagged rocky outline is seen." Again, with regard to Chinese Turkistan:—"If you could get a bird's-eye view of Chinese Turkistan, you would see a great bare desert surrounded on three sides by barren mountains, and at their bases you would see some vivid green spots, showing out sharp and distinct like blots of green paint dropped on to a sepia picture. In the western end round Kashgar and Yarkand the cultivation is of greater extent and more continuous than in the eastern half, where the oases are small and separated from each other by 15 or 20 miles of desert. These oases are, however, extraordinarily fertile, every scrap of land that can be cultivated is used up, and every drop of water is drained off from the stream and used for irrigation." At the conclusion of Monday's meeting of the Royal Geographical Society, General J. T. Walker proposed, and Sir Henry Rawlinson seconded, that the peak in the Karakorum known as K2, 28,500 feet high, be baptized Mount Godwin-Austen—a proposal heartily approved by the meeting.

THE Paris Geographical Society has awarded gold medals to the Rev. P. Roblet, for his map of Madagascar; to MM. Bonvalot, Capus, and Pépin, for their journeys in Kafiristan and the Pamir; to M. Chaffanjon, for his exploration of the sources of the Orinoco.

GENERAL PRJEVALSKY will start in August next on his fourth journey in Central Asia. His ultimate destination will be Lhassa, the capital of Tibet, and he will be equipped for two years' travel. He will be accompanied by an escort of twenty-eight persons, including twelve Cossacks, and two scientific companions, Lieut. Robrowsky and Sub-Lieut. Koslow.

THE PYGMY RACES OF MEN.[1]

II.

LIKE all other human beings existing at present in the world, however low in the scale of civilization, the social life of the Andamanese is enveloped in a complex maze of unwritten law or custom, the intricacies of which are most difficult for any stranger to unravel. The relations they may or may not marry, the food they are obliged or forbidden to partake of at particular epochs of life or seasons of the year, the words and names they may or may not pronounce: all these, as well as their traditions, superstitions, and beliefs, their occupations, games, and amusements of which they seem to have had no lack, would take far too long to describe here; but, before leaving these interesting people, I may quote an observation of Mr. Man's, which, unless he has seen them with too *couleur-de-rose* eyesight, throws a very favourable light upon the primitive unsophisticated life of these poor little savages, now so ruthlessly broken into and destroyed by the exigencies of our ever-extending Empire.

"It has been asserted," Mr. Man says, "that the 'communal marriage' system prevails among them, and that 'marriage is nothing more than taking a female slave'; but, so far from the contract being regarded as a merely temporary arrangement, to be set aside at the will of either party, no incompatibility of temper or other cause is allowed to dissolve the union; and while bigamy, polygamy, polyandry, and divorce are unknown, conjugal fidelity till death is not the exception but the rule, and matrimonial differences, which, however, occur but rarely, are easily settled with or without the intervention of friends." In fact, Mr. Man goes on to say, "One of the most striking features of their social relations is the marked equality and affection which subsists between husband and wife," and "the consideration and respect with which women are treated might with advantage be emulated by certain classes in our own land."

It should also be mentioned that cannibalism and infanticide, two such common incidents of savage life, were never practised by them.

We must now pass to the important scientific question, Who are the natives of the Andaman Islands, and where, among the other races of the human species, shall we look for their nearest relations?

It is due mainly to the assiduous researches into all the documentary evidence relating to the inhabitants of Southern Asia and the Indian Archipelago, conducted through many years by M. de Quatrefages, in some cases with the assistance of his colleague M. Hamy, that the facts I am about to put before you have been prominently brought to light, and their significance demonstrated.

It is well known that the greater part of the large island of New Guinea, and of the chain of islands extending eastwards and southwards from it, including the Solomon Islands, the New Hebrides, and New Caledonia, and also the Fijis, are still inhabited mainly by people of dark colour, frizzly hair, and many characters allying them to the Negroes of Africa. These constitute the race to which the term Melanesian is commonly applied in this country, or Oceanic Negroes, the "Papouas" of Quatrefages. Their area at one time was more extensive than it is now, and has been greatly encroached upon by the brown, straight-haired Polynesian race with Malay affinities, now inhabiting many of the more important islands of the Pacific, and the mingling of which with the more aboriginal Melanesians in various proportions has been a cause, among others, of the diverse aspect of the population on many of the islands in this extensive region. These Papouas, or Melanesians, however, differ greatly from the Andamanese in many easily defined characters; which are, especially, their larger stature, their long, narrow, and high skulls, and their coarser and more Negro-like features. Although undoubtedly allied, we cannot look to them as the nearest relations of our little Andamanese.

When the Spaniards commenced the colonization of the Philippines, they met with, in the mountainous region in the interior of the Island of Luzon, besides the prevailing native population, consisting of Tagals of Malay origin, very small people, of black complexion, with the frizzly hair of the African Negroes. So struck were they with the resemblance, that they called them "Negritos del Monte" (little Negroes of the mountain). Their local name was Aigtas, or Inagtas, said to signify "black," and from which the word Aëta, generally now applied to them, is derived. These people have lately been studied by two French travellers, M. Marche and Dr. Montano; the result of their measurements gives 4 feet $8\frac{3}{4}$ inches as the average height of the men, and 4 feet $6\frac{1}{2}$ inches the average for the women. In many of their moral characteristics they resemble the Andamanese. The Aëtas are faithful to their marriage vows, and have but one wife. The affection of parents for children is very strong, and the latter have for their father and mother as much love and respect. The marriage ceremony, according to M. Montano, is very remarkable. The affianced pair climb two flexible trees placed near to each other. One of the elders of the tribe bends them towards each other. When

[1] A Lecture delivered at the Royal Institution on Friday evening, April 13, 1888, by Prof. Flower, C.B., LL.D., F.R.S., Director of the Natural History Departments of the British Museum. Continued from p. 45.

their heads touch, the marriage is legally accomplished. A great *fête*, with much dancing, concludes the ceremony.

It was afterwards found that the same race existed in other parts of the archipelago, Panay, Mindanao, &c., and that they entirely peopled some little islands—among others, Bougas Island, or "Isla de los Negros."

As the islands of these eastern seas have become better known, further discoveries of the existence of a small Negroid population have been made in Formosa, in the interior of Borneo, the Sandal Islands (Sumba), Xulla, Bourou, Ceram, Flores, Solor, Pantar, Lomblem, Ombay, the eastern peninsula of Celebes, &c. In fact, Sumatra and Java are the only large islands of this great area which contain no traces of them except some doubtful cross-breeds, and some remains of an industry which appears not to have passed beyond the Age of Stone.

The Sunda Islands form the southern limit of the Negrito area; Formosa, the last to the north, where the race has preserved all its characters. But beyond this, as in Lew-Chew, and even the south-east portion of Japan, it reveals its former existence by the traces it has left in the present population. That it has contributed considerably to form the population of New Guinea is unquestionable. In many parts of that great island, small round-headed tribes live more or less distinct from the larger and longer-headed people who make up the bulk of the population.

But it is not only in the islands that the Negrito race dwelt. Traces of them are found also on the mainland of Asia, but everywhere under the same conditions: in scattered tribes, occupying the more inaccessible mountainous regions of countries otherwise mainly inhabited by other races, and generally in a condition more or less of degradation and barbarism, resulting from the oppression with which they have been treated by their invading conquerers; often, moreover, so much mixed that their original characters are scarcely recognizable. The Semangs of the interior of Malacca in the Malay peninsula, the Sakays from Perak, the Moys of Annam, all show traces of Negrito blood. In India proper, especially among the lowest and least civilized tribes, not only of the central and southern districts, but even almost to the foot of the Himalayas, in the Punjab, and even to the west side of the Indus, according to Quatrefages, frizzly hair, Negro features, and small stature, are so common that a strong argument can be based on them for the belief in a Negrito race forming the basis of the whole pre-Aryan, or Dravidian as it is generally called, population of the peninsula. The crossing that has taken place with other races has doubtless greatly altered the physical characters of this people, and the evidences of this alteration manifest themselves in many ways; sometimes the curliness of the hair is lost by the admixture with smooth straight-haired races, while the black complexion and small stature remain; sometimes the stature is increased, but the colour which seems to be one of the most persistent of characteristics, remains.

The localities in which these people are found in their greatest purity, either in almost inaccessible islands, as on the Andamans, or elsewhere in the mountainous ranges of the interior only; their social positions and traditions, wherever they exist—all point to the fact that they were the earliest inhabitants; and that the Mongolian and Malay races on the east, and the Aryans on the west, which are now so rapidly exterminating and replacing them, are later comers into the land, exactly as, in the greater part of the Pacific Ocean, territory formerly occupied by the aboriginal dark, frizzly-haired Negroid Melanesians has been gradually and slowly invaded by the brown Polynesians, who in their turn, but by a much more rapid process, are being replaced by Europeans.

We now see what constitutes the great interest of the Andamanese natives to the student of the ethnological history of the Eastern world. Their long isolation has made them a remarkably homogeneous race, stamping them all with a common resemblance not seen in the mixed races generally met with in continental areas. For although, as with most savages, marriages within the family (using the term in a very wide sense) are most strictly forbidden, all such alliances have necessarily been confined to natives of the islands. They are the least modified representatives of the people who were, as far as we know, the primitive inhabitants of a large portion of the earth's surface, but who are now verging on extinction. It is, however, not necessary to suppose that the Andaman Islanders give us the exact characters and features of all the other branches of the race. Differences in detail doubtless existed—differences which are almost always sure to arise whenever races become isolated from each other for long periods of time.

In many cases the characters of the ancient inhabitants of a land have been revealed to us by the preservation of their actual remains. Unfortunately we have as yet no such evidence to tell us of the former condition of man in Southern Asia. We may, however, look upon the Andamanese, the Aëtas, and the Semangs, as living fossils; and by their aid conjecture the condition of the whole population of the land in ancient times. It is possible, also, to follow Quatrefages, and to see in them the origin of the stories of the Oriental pygmies related by Ctesias and by Pliny.

We now pass to the continent of Africa, in the interior of which the pygmies of Homer, Herodotus, and Aristotle have generally been placed. Africa, as is well known, is the home of another great branch of the black, frizzly-haired, or Ethiopian division of the human species, who do, or did till lately, occupy the southern two-thirds of this great continent, the northern third being inhabited by Hamite and Semite branches of the great white or Caucasian primary division of the human species, or by races resulting from the mixture of them and the Negroes. Besides the true Negro, there has long been known to exist in the southern part of the continent a curiously modified type, consisting of the Hottentots, and the Bushmen—Bosjesmen (men of the woods) of the Dutch colonists—the latter of whom, on account of their small size, come within the scope of the present subject. They lead the lives of the most degraded of savages, dwelling among the rocky and more inaccessible mountains of the interior, making habitations of the natural caves, subsisting entirely by the chase, being most expert in the use of the bow and arrow, and treated as enemies and outcasts by the surrounding and more civilized tribes, whose flocks and herds they show little respect for when other game is not within reach. The physical characters of these people are well known, as many specimens have been brought to Europe alive for the purpose of exhibition. Their hair shows the extreme of the frizzly type, being shorter and less abundant than that of the ordinary Negro; it has the appearance of growing in separate tufts, which coil up together into round balls compared to "peppercorns." The yellow complexion differs from that of the Negro, and, combined with the wide cheek-bones and form of the eyes, so much recalls that of certain of the pure yellow races that some anthropologists are inclined to trace true Mongolian affinities and admixture, although the extreme crispness of the hair makes such a supposition almost impossible. The width of the cheek-bones and the narrowness of the forehead and the chin give a lozenge shape to the front view of the face. The forehead is prominent and straight; the nose extremely flat and broad, more so than in any other race, and the lips prominent and thick, although the jaws are less prognathous than in the true Negro races. The cranium has many special characters by which it can be easily distinguished from that of any other. It has generally a very feminine, almost infantile, appearance, though the capacity of the cranial cavity is not the smallest, exceeding that of the Andamanese. In general form the cranium is rather oblong than oval, having straight sides, a flat top, and especially a vertical forehead, which rises straight from the root of the nose. It is moderately dolichocephalic or rather mesaticephalic, the average of the index of ten specimens being 75·4. The height is in all considerably less than the breadth, the average index being 71·1. The glabella and infra-orbital ridges are little developed except in the oldest males. The malar bones project much forwards, and the space between the orbits is very wide and flat. The nasal bones are extremely small and depressed, and the aperture wide; the average nasal index being 60·8, so they are the most platyrhine of races.

With regard to the stature, we have not yet sufficient materials for giving a reliable average. Quatrefages, following Barrow, gives 4 feet 6 inches for the men, and 4 feet for the women, and speaks of one individual of the latter sex, who was the mother of several children, measuring only 3 feet 9 inches in height; but later observations (still, however, insufficient in number) give a rather larger stature: thus Topinard places the average at 1·404 metre, or 4 feet 7½ inches; and Fritsch, who measured six male Bushmen in South Africa, found their mean height to be 1·444 metre, or nearly 4 feet 9 inches. It is probable that, taking them all together, they differ but little in this respect from the Andamanese, although in colour, in form of head, in features, and in the proportions of the body, they are widely removed from them.

There is every reason to believe that these Bushmen represent the earliest race of which we have, or are ever likely to have, any knowledge, which inhabited the southern portion of the African continent, but that long before the advent of Europeans upon the scene, they had been invaded from the north by Negro tribes, who, being superior in size, strength, and civilization, had taken possession of the greater part of their territories, and mingling freely with the aborigines, had produced the mixed race called Hottentots, who retained the culture and settled pastoral habits of the Negroes, with many of the physical features of the Bushmen. These, in their turn, encroached upon by the pure-bred Bantu Negroes from the north, and by the Dutch and English from the south, are now greatly diminished, and indeed threatened with the same fate that will surely soon befall the scanty remnant of the early inhabitants who still retain their primitive type.

At present the habitat of the Bushman race is confined to certain districts in the south-west of Africa, from the confines of the Cape Colony, as far north as the shores of Lake Ngami. Further to the north the great equatorial region of Africa is occupied by various Negro tribes, using the term in its broadest sense, but belonging to the divisions which, on account of peculiarities of language, have been grouped together as Bantu. They all present the common physical characteristics typical of the Negro race, only two of which need be specially mentioned here—medium or large stature, and dolichocephalic skull (average cranial index about 73·5).

It is at various scattered places in the midst of these, that the only other small people of which I shall have to speak, the veritable pygmies of Homer, Herodotus, and Aristotle, according to Quatrefages, are still to be met with.[1]

The first notice of the occurrence of these in modern times is contained in "The strange adventures of Andrew Battell of Leigh in Essex, sent by the Portugals prisoner to Angola, who lived there, and in the adjoining regions near eighteen yeares" (1589 to 1607), published in "Purchas his Pilgrimes" (1625), lib. vii. chap. iii. p. 983:—

"To the north-east of *Mani-Kesock*, are a kind of little people, called *Matimbas;* which are no bigger than Boyes of twelve yeares old, but very thicke, and live only upon flesh, which they kill in the woods with their bows and darts. They pay tribute to *Mani-Kesock*, and bring all their elephants' teeth and tayles to him. They will not enter into any of the *Maramba's* houses, nor will suffer any to come where they dwell. And if by chance any *Maramba* or people of *Longo* pass where they dwell, they will forsake that place, and go to another. The women carry Bows and Arrows as well as the men. And one of these will walk in the woods alone and kill the Pongos with their poysoned Arrows."

Battell's narrative, it should be said, is generally admitted as having an air of veracity about it not always conspicuous in those of travellers of his time. In addition to the observations on the human inhabitants, it contains excellent descriptions of animals, as the pongo or gorilla, and the zebra, now well known, but in his day new to Europeans.

Dapper, in a work called "Description de la Basse Ethiopie," published at Amsterdam in 1686, speaks of a race of dwarfs inhabiting the same region, which he calls *Mimos* or *Bakke-Bakke*, but nothing further was heard of these people until quite recent times. A German scientific expedition to Loango, the results of which were published in the *Zeitschrift für Ethnologie*, 1874, and in Hartmann's work, "Die Negritier," obtained, at Chinchoxo, photographs and descriptions of a dwarf tribe called "Baboukos," whose heads were proportionally large and of roundish form (cephalic index of skull, 78 to 81). One individual, supposed to be about forty years of age, measured 1·365 metre, rather under 4 feet 6 inches.

Dr. Touchard, in a "Notice sur le Gabon," published in the *Revue Maritime et Coloniale* for 1861, describes the recent destruction of a population established in the interior of this country and to which he gives the name of "Akoa." They seem to have been exterminated by the M'Pongos in their expansion towards the west. Some of them, however, remained as slaves at the time of the visit of Admiral Fleuriot de Langle, who in 1868 photographed one (measuring about 4 feet 6 inches high) and brought home some skulls, which were examined by Hamy, and all proved very small and sub-brachycephalic.

[1] The scattered information upon this subject was first collected together by Hamy in his "Essai de co-ordination des Matériaux récemment recueillis sur l'ethnologie des Négrilles ou Pygmées de l'Afrique équatoriale," *Bull. Soc. d'Anthropologie de Paris*, tome ii. (ser. iii.), 1879, p. 79.

Another tribe, the M'Boulous, inhabiting the coast north of the Gaboon River, have been described by M. Marche as probably the primitive race of the country. They live in little villages, keeping entirely to themselves, though surrounded by the larger Negro tribes, M'Pongos and Bakalais, who are encroaching upon them so closely that their numbers are rapidly diminishing. In 1860 they were not more than 3000; in 1879 much less numerous. They are of an earthy-brown colour, and rarely exceed 1·600 metre in height (5 feet 3 inches). In the rich collections of skulls made by Mr. R. B. Walker and by M. Du Chaillu, from the coast of this region, are many which are remarkable for their small size and round form. Of many other notices of tribes of Negroes of diminutive size, living near the west coast of Equatorial Africa, I need only mention that of Du Chaillu, who gives an interesting account of his visit to an Obongo village in Ashango-land, between the Gaboon and the Congo; although unfortunately, owing to the extreme shyness and suspicion of the inhabitants, he was allowed little opportunity for anthropological observations. He succeeded, however, in measuring one man and six women; the height of the former was 4 feet 6 inches, the average of the later 4 feet 8 inches.[1]

Far further into the interior, towards the centre of the region contained in the great bend of the Congo or Livingstone River, Stanley heard of a numerous and independent population of dwarfs, called "Watwas," who, like the Batimbas of Battell, are great hunters of elephants, and use poisoned arrows. One of these he met with at Ikondu was 4 feet 6½ inches high, and of a chocolate-brown colour.[2] More recently Dr. Wolff describes under the name of "Batouas" (perhaps the same as Stanley's Watwas), a people of lighter colour than other Negroes, and never exceeding 1·40 metres (4 feet 7 inches) high, but whose average is not more than 1·30 (4 feet 3 inches), who occupy isolated villages scattered through the territory of the Bahoubas, with whom they never mix.[3]

Penetrating into the heart of Africa from the north-east, in 1870, Dr. George Schweinfurth first made us acquainted with a diminutive race of people who have since attained a considerable anthropological notoriety. They seem to go by two names in their own country, *Akka* and *Tikki-tikki*, the latter reminding us curiously of Dapper's Bakke-bakke, and the former, more singularly still, having been read by the learned Egyptologist, Mariette, by the side of the figure of a dwarf in one of the monuments of the early Egyptian Empire.

It was at the court of Mounza, king of the Monbuttu, that Schweinfurth first met with the Akkas. They appear to live under the protection of that monarch, who had a regiment of them attached to his service, but their real country was further to the south and west, about 3° N. lat. and 25° E. long. From the accounts the traveller received they occupy a considerable territory, and are divided into nine distinct tribes, each having its own king or chief. Like all the other pygmy African tribes, they live chiefly by the chase, being great hunters of the elephant, which they attack with bows and arrows.

In exchange for one of his dogs, Schweinfurth obtained from Mounza one of these little men, whom he intended to bring to Europe, but who died on the homeward journey at Berber. Unfortunately all the measurements and observations which were made in the Monbuttu country by Schweinfurth perished in the fire which destroyed so much of the valuable material he had collected. His descriptions of their physical characters are therefore chiefly recollections. Other travellers—Long, Marno, and Vossion—though not penetrating as far as the Akka country, have given observations upon individuals of the race they have met with in their travels. The Italian Miani, following the footsteps of Schweinfurth into the Monbuttu country, also obtained, by barter, two Akka boys, with the view of bringing them to Europe. He himself fell a victim to the fatigues of the journey and climate, but left his collections, including the young Akkas, to the Italian Geographical Society. Probably no two individuals of a savage race have been so much honoured by the attentions of the scientific world. First at Cairo, and afterwards in Italy, Tebo (or Thibaut) and Chairallah, as they were named, were described, measured, and photographed, and have been the subjects of a library of memoirs, their bibliographers including the names of Owen, Panceri, Cornalia, Mantegazza, Giglioli and Zannetti, Broca, Hamy, and de Quatrefages. On their arrival in Italy they were presented to the King and Queen, introduced into the

[1] "A Journey to Ashango-land," 1867, p. 3[illegible]5.
[2] "Through the Dark Continent," vol. ii.
[3] *La Gazette Géographique*, 1887, p. 153, quoted by Quatrefages.

nost fashionable society, and finally settled down as members of the household of Count Miniscalchi Erizzo, at Verona, where hey received a European education, and performed the duties of pages.

In reply to an inquiry addressed to my friend Dr. Giglioli, of Florence, I hear that Thibaut died of consumption on January 28, 1883, being then about twenty-two years of age, and was buried in the cemetery at Verona. Unfortunately no scientific examination of the body was allowed, but whether Chairallah still lives or not I have not been able to learn. As Giglioli has not heard of his death, he presumes that he is still living in Count Miniscalchi's palace.

One other specimen of this race has been the subject of careful observation by European anthropologists—a girl named Saida, brought home by Romolo Gessi (Gordon's lieutenant), and who is still, or was lately, living at Trieste as servant to M. de Gessi.

The various scattered observations hitherto made are obviously insufficient to deduce a mean height for the race, but he nearest estimate that Quatrefages could obtain is about 4 feet 7 inches for the men, and 4 feet 3 inches for the women, decidedly inferior, therefore, to the Andamanese. With egard to their other characters, their hair is of the most frizzly ind, their complexion lighter than that of most Negroes, but he prognathism, width of nose, and eversion of lips characteristic f the Ethiopian branch of the human family are carried to an xtreme degree, especially if Schweinfurth's sketches can be rusted. The only essential point of difference from the ordinary Negro, except the size, is the tendency to shortening and breadth f the skull, although it by no means assumes the "almost pherical" shape attributed to it by Schweinfurth.

Some further information about the Akkas will be found in ie work, just published, of the intrepid and accomplished raveller in whose welfare we are now so much interested, Dr. Emin Pasha, Gordon's last surviving officer in the Soudan, who in the course of his explorations spent some little time lately n the country of the Monbuttu. Here he not only met with ving Akkas, one of whom he apparently still retains as a omestic in his service, and of whose dimensions he has sent me most detailed account, but he also, by watching the spots where wo of them had been interred, succeeded in obtaining their keletons, which, with numerous other objects of great scientific nterest, safely arrived at the British Museum in September of ast year. I need hardly say that actual bones, clean, imperishble, easy to be measured and compared, not once only, but ny number of times, furnish the most acceptable evidence that n anthropologist can possess of many of the most important hysical characters of a race. There we have facts which can ways be appealed to in support of statements and inferences ased on them. Height, proportions of limbs, form of head, haracters of the face even, are all more rigorously determined om the bones than they can be on the living person. Therefore ie value of these remains, imperfect as they unfortunately are, nd of course insufficient in number for the purpose of establishing verage characters, is very great indeed.

As I have entered fully into the question of their peculiarities sewhere, I can only give now a few of the most important nd most generally to be understood results of their examination. he first point of interest is their size. The two skeletons are oth those of full-grown people, one a man, the other a woman. here is no reason to suppose that they were specially selected exceptionally small; they were clearly the only ones which min had an opportunity of procuring; yet they fully bear out, ore than bear out, all that has been said of the diminutive e of the race. Comparing the dimensions of the bones, one one, with those of the numerous Andamanese that have passed rough my hands, I find both of these Akkas smaller, not than e average, but smaller than the smallest; smaller also than y Bushman whose skeleton I am acquainted with, or whose mensions have been published with scientific accuracy. In t, they are both, for they are nearly of a size, the smallest rmal human skeletons which I have seen, or of which I can d any record. I say normal, because they are thoroughly ll grown and proportioned, without a trace of the deformity nost always associated with individual dwarfishness in a taller e. One only, that of the female, is sufficiently perfect for iculation. After due allowance for some missing vertebræ, and the intervertebral spaces, the skeleton measures from the wn of the head to the ground exactly 4 feet, or 1·218 metre. out half an inch more for the thickness of the skin of the head and soles of the feet would complete the height when alive. The other (male) skeleton was (judging by the length of the femur) about a quarter of an inch shorter.

The full-grown woman of whom Emin gives detailed dimensions is stated to be only 1·164 metre, or barely 3 feet 10 inches.[1] These heights are all unquestionably less than anything that has been yet obtained based upon such indisputable data. One very interesting and almost unexpected result of a careful examination of these skeletons is that they conform in the relative proportions of the head, trunk, and limbs, not to dwarfs, but to full-sized people of other races, and they are therefore strikingly unlike the stumpy, long-bodied, short-limbed, large-headed pygmies so graphically represented fighting with their lances against the cranes on ancient Greek vases.

The other characters of these skeletons are Negroid to an intense degree, and quite accord with what has been stated of their external appearance. The form of the skull, too, has that sub-brachycephaly which has been shown by Hamy to characterize all the small Negro populations of Central Africa. It is quite unlike that of the Andamanese, quite unlike that of the Bushmen. They are obviously Negroes of a special type, to which Hamy has given the appropriate term of *Negrillo*. They seem to have much the same relation to the larger longer-headed African Negroes that the small round-headed Negritos of the Indian Ocean have to their larger longer-headed Melanesian neighbours.

At all events, the fact now seems clearly demonstrated that at various spots across the great African continent, within a few degrees north and south of the equator, extending from the Atlantic coast to near the shores of the Albert Nyanza (30° E. long.), and perhaps, if some indications which time will not allow me to enter into now (but which will be found in the writings of Hamy and Quatrefages), even further to the east, south of the Galla land, are still surviving, in scattered districts, communities of these small Negroes, all much resembling each other in size, appearance, and habits, and dwelling mostly apart from their larger neighbours, by whom they are everywhere surrounded. Our information about them is still very scanty, and to obtain more would be a worthy object of ambition for the anthropological traveller. In many parts, especially at the west, they are obviously holding their own with difficulty, if not actually disappearing, and there is much about their condition of civilization, and the situations in which they are found, to induce us to look upon them, as in the case of the Bushmen in the south and the Negritos in the east, as remains of a population which occupied the land before the incoming of the present dominant races. If the account of the Nasamonians related by Herodotus is accepted as historical, the river they came to, "flowing from west to east," must have been the Niger, and the northward range of the dwarfish people far more extensive twenty-three centuries ago than it is at the present time.

This view opens a still larger question, and takes us back to the neighbourhood of the south of India as the centre from which the whole of the great Negro race spread, east over the African continent, and west over the islands of the Pacific, and to our little Andamanese fellow subjects as probably the least modified descendants of the primitive members of the great branch of the human species characterized by their black skins and frizzly hair.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—In a recent discussion on the proposed appropriation of the whole of the Botanic Gardens site for Natural Science Departments, it seemed to be generally agreed that the Mechanical Department ought to be removed from a locality where it must cause vibrations injurious to microscopical or physical research. The suggested removal of the Herbarium to the Botanic Gardens was disapproved of by the Professor and his Assistant-Curator. The proposed appropriation of the present Chemical Rooms for Pathology was generally approved. Mr. J. W. Clark emphatically condemned the present Museum of Human Anatomy and Surgery as a discredit to the University. Prof. Hughes further put in a claim that the Geological Museum should extend to the extreme east of the site, and that the erection of the buildings should be begun at once.

[1] In his letters Emin speaks of an Akka man as "3 feet 6 inches" high, though this does not profess to be a scientifically accurate observation, as does the above. He says of this man that his whole body was covered by thick, stiff hair, almost like felt, as was the case with all the Akkas he had yet examined.

The first Harkness Scholarship for Geology and Palæontology is to be awarded in June next; names of candidates are to be sent in by May 31 next. Candidates must be Bachelors of Arts of not more than two-and-a-half years' standing.

The Sheepshanks Astronomical Exhibition will be awarded next December, at Trinity College. It is open to all undergraduates of the University, but the person elected must become a member of Trinity College. The conditions may be learnt from Dr. Glaisher, Trinity College.

SOCIETIES AND ACADEMIES.

London.

Royal Society, April 26.—"On the Development of the Electric Organ of *Raia batis*." By J. C. Ewart, M.D., Regius Professor of Natural History, University of Edinburgh. Communicated by J. Burdon Sanderson, F.R.S.

The paper consists of a short description of the electric organs found in the skate genus, and of an account of the development of the electric organ of the common grey skate (*Raia batis*).

It is shown that while in some skates (*e.g.*, *Raia batis*) the organ is made up of disk-shaped bodies, in others (*e.g.*, *Raia fullonica*) it consists of numerous cup-shaped structures provided with long or short stems.

The disks (with the development of which the paper chiefly deals) consist essentially of three layers, viz. (1) an electric plate in front in which the nerves end; (2) a striated layer which supports the electric plate; and (3) an alveolar layer, posterior to which is a thick cushion of gelatinous tissue. Each disk is formed in connection with a muscular fibre. In young embryos there is no indication of an electric organ, but in an embryo 6 or 7 cm. in length, some of the muscular fibres at each side of the notochord are found in process of conversion into long slender clubs having their heads nearest the root of the tail.

The club-stage having been reached, the muscular fibre next assumes the form of a mace, and, later, the anterior end further expands to form a relatively large disk, while the remainder of the original fibre persists as a slender ribbon-shaped appendage. As the head of the club enlarges to form a disk, it passes through an indistinct cup-stage, which somewhat resembles the cups of the adult *Raia fullonica*, hence it may be inferred that in *Raia fullonica* the organ has been arrested in its development. The conversion of the muscular fibre into a club is largely caused by the increase, at its anterior end, of muscle-corpuscles. These corpuscles eventually arrange themselves, either in front of the head of the club, to give rise to the electric plate, or they migrate backwards to form at the junction of the head of the club with its stem the alveolar layer. The striated layer, which is from the first devoid of nuclei, seems to be derived from the anterior striated portion of the club.

The gelatinous tissue between the disks, and the connective tissue investing them, are derived from the embryonic connective tissue corpuscles, which exist in great numbers around the clubs and developing disks.

May 3.—"On the Relations of the Diurnal Barometric Maxima to certain Critical Conditions of Temperature, Cloud, and Rainfall." By Henry F. Blanford, F.R.S.

The author refers to an observation of Lamont's that the diurnal barometric variation appears to be compounded of two distinct elements, viz. a wave of diurnal period, which is very variable in different places, and which appears to depend on the horizontal and vertical movements of the atmosphere and changes in the distribution of its mass, and a semi-diurnal element which is remarkably constant and seems to depend more immediately on the action of the sun. Then, referring to the theory of the semi-diurnal variation, originally put forward by Espy, and subsequently by Davies and Kreil, the author points out that the morning maximum of pressure approximately coincides with the instant when the temperature is rising most rapidly. This is almost exactly true at Prague, Yarkand, both in winter and summer, and in winter months at Melbourne. At the tropical stations, Bombay, Calcutta, and Batavia, and at Melbourne in the summer, the barometric maximum follows the instant of most rapid heating by a shorter or longer interval; and the author remarks that this may probably be attributed to the action of convection, which must accelerate the time of most rapid heating near the ground surface; while the barometric effect, if real, must be determined by the condition of the atmosphere up to a great height. With reference to Lamont's demonstration of the failure of Espy's theory, a condition is pointed out which alters the data of the problem, viz. the resistance that must be offered to the passage of the pressure-wave through the extremely cold and highly attenuated atmospheric strata, whose existence is proved by the phenomena of luminous meteors.

With respect to the evening maximum of pressure, it is pointed out that very generally, and especially in India, and also at Melbourne, there is a strongly-marked minimum in the diurnal variation of cloud between sunset and midnight, which, on an average, as at Allahabad and Melbourne, coincides with the evening maximum of the barometer. A similar coincident minimum, even more strongly marked, characterizes the diurnal variation of the rainfall at Calcutta and Batavia in their respective rainy seasons. In the author's opinion these facts seem to point to a compression and dynamic heating of the cloud-forming strata, and he points to the existence of a small irregularity in the diurnal temperature curves of Prague, Calcutta, and Batavia, which may possibly be due to such action. It is further remarked that the evening maximum about coincides with the time when the evening fall of temperature, after a rapid reduction between 6 or 7 and 10 p.m., becomes nearly uniform in rate, and it is suggested that the former may possibly be determined by the check of the rate of collapse of the cooling atmosphere. But it is observed that both the morning and evening waves of pressure probably involve other elements than the forced waves, and are in part rhythmic repetitions of previous waves.

Geological Society, April 25.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—Report on the recent work of the Geological Survey in the North-West Highlands of Scotland, based on the field-notes and maps of Messrs. Peach, Horne, Gunn, Clough, Hinxman, and Cadell. Communicated by Dr. A. Geikie. At the outset a review was given of the researches of other observers, in so far as they forestalled the conclusions to which the Geological Survey had been led. Reference was made to the observations of Macculloch, Hay Cunningham, C. W. Peach, and Salter; to the prolonged controversy between Sir Roderick Murchison and Prof. Nicol; to the contributions of Hicks, Bonney, Hudleston, Callaway, Lapworth, Teall, and others. It was shown that Nicol was undoubtedly right in maintaining that there was no conformable sequence from the fossiliferous quartzites and limestones into the eastern schists. It was also pointed out that the conclusions of Prof. Lapworth regarding the nature and origin of the eastern schists involve an important departure from Nicol's position, and are practically identical with those obtained independently by the Geological Survey. The results of the recent survey work among the Archæan rocks may be thus summarized: (1) the eruption of a series of igneous rocks of a basic type in which pegmatites were formed; (2) the development of rude foliation in these masses, probably by mechanical movement, and their arrangement in gentle anticlines and synclines, the axes of which generally run N.E. and S.W.; (3) the injection of igneous materials, mainly in the form of dykes, into the original gneisses, composed of (*a*) basalt rocks, (*b*) peridotites and palæopicrites, (*c*) microcline-mica rocks, (*d*) granites; (4) the occurrence of mechanical movements giving rise to disruption-lines trending N.W. and S.E., E. and W., N.E. and S.W.; (5) the effects of these movements on the dykes were to change the basalt-rocks into diorites and hornblende-schists, the peridotites and palæopicrites into talcose schists, the microcline-mica rocks into mica schists, and the granites into granitoid gneiss; (6) the effects on the gneiss resulted in the formation of sharp folds trending generally N.W. and S.E., the partial or complete reconstruction of the original gneiss along the old foliation-planes, and finally the development of newer schistosity more or less parallel with the prominent disruption-lines. There is an overwhelming amount of evidence to prove that all these various changes had been superinduced in the Archæan rocks in pre-Cambrian time. After reviewing the facts bearing on the denudation of the Archæan land-surface, the order of succession and thickness of the Cambrian strata were given, from which it is apparent that the deposits gradually increase in thickness as we pass southwards from Durness to Loch Broom. Prior to the deposition of the Silurian sediments the Cambrian strata were folded and extensively denuded. By these means various Cambrian outliers were formed far to the east of the present limits of the formation. The order of succession of the Silurian strata along the line of complicated structure from

Eriboll to Ullapool was described, reference being made to the further subdivision of the "Pipe-rock" and the Ghrudaidh Limestones (Group I. of Durness section). None of the richly fossiliferous zones of Durness is met with along this line, as they occupy higher horizons. An examination of the fossils recently obtained by the Geological Survey from the Durness Limestones confirms Salter's conclusions that they are distinctly of an American type, the Sutherland quartzites and limestones being represented by the Potsdam Sandstones and Calciferous Sand Group of North America. After the deposition of the limestones, the Cambrian and Silurian strata were pierced by igneous rocks, mainly in the form of sheets, producing important alterations in the sedimentary deposits by contact-metamorphism, the quartzites becoming crystalline, and the limestones being converted into marble. When this outburst of volcanic activity had ceased, terrestrial displacements ensued on a stupendous scale. By means of powerful thrusts the Silurian strata were piled on each other, and huge slices of the old Archæan platform, with the Cambrian and Silurian strata resting on it, were driven westwards for miles. With the view of illustrating the extraordinary complications produced by these movements, a series of horizontal sections was described, drawn across the line between Eriboll and Ullapool. The evidence relating to regional metamorphism was next referred to, from which it is obvious that with each successive maximum thrust there is a progressive amount of alteration in the displaced masses, as the observer passes eastwards to the higher thrust-planes. Eventually the Archæan gneiss is so deformed that the pre-Cambrian foliation disappears and is replaced by new divisional planes; the Cambrian grits and shales are converted into schists; the Silurian quartzites into quartz-schists; the limestones become crystalline; the sheets of intrusive felsite, diorite, and granitoid rock pass into sericite schist, hornblende-schist, and augen-gneiss respectively. These researches furnish a vast amount of evidence in support of the theory that regional metamorphism is due to the dynamical and chemical effects of mechanical movement acting on crystalline and clastic rocks. It is also clear that regional metamorphism need not be confined to any particular geological period, because in the N.W. Highlands, both in pre Cambrian time and after the deposition of the Durness Limestone (Lower Silurian), crystalline schists and gneiss were produced on a magnificent scale. After the reading of this Report, the Survey was congratulated on its work by the President, Prof. Lapworth, Prof. Judd, and other speakers.—On the horizontal movements of rocks, and the relation of these movements to the formation of dykes and faults, and to denudation and the thickening of strata, by Mr. William Barlow.—Notes on a recent discovery of *Stigmaria ficoides* at Clayton, Yorkshire, by Mr. Samuel A. Adamson.

Zoological Society, April 30.—Fifty-ninth Anniversary Meeting.—Prof. Flower, F.R.S., President, in the chair.—After the Auditors' Report had been read, and some other preliminary business had been transacted, the Report of the Council on the proceedings of the Society during the year 1887 was read by Mr. P. L. Sclater, F.R.S., the Secretary of the Society. It stated that the number of Fellows on January 1, 1888, was 3104, showing a decrease of 42 as compared with the corresponding period in 1887. A large number of valuable communications received at the usual scientific meetings held during the session of 1887 had been published in the annual volume of Proceedings, which contained 730 pages, illustrated by 55 plates. Besides this, one part of the twelfth volume, viz. Part C, of the Society's quarto Transactions, illustrated by seven plates, had been issued, and several other parts of Transactions were in a forward state. The volume of the *Zoological Record* for 1886 had been sent out in the month of January of this year to about 140 subscribers. The new edition of the Library Catalogue, spoken of in the last Annual Report as ready for issue had been published last summer. Two important additions had been made to the buildings in the Society's Gardens during the past year. The first of these, the wolves' and foxes' dens, which were commenced in 1886, had been erected by the Society's staff, under the supervision of Mr. Trollope, by whom the plans were drawn, and completed in November last. The second addition was a new aviary for flying birds which had been erected on the water-fowls' lawn, opposite the eastern aviary. This aviary is 105 feet long, 62 feet broad, and 27 feet high in the centre of the roof, which is formed of galvanized wire. The visitors to the Society's Gardens during the year 1887 had been altogether 562,898; the corresponding number in 1886 was 639,674. Mr. F. E. Beddard, Prosector to the Society, had been appointed Davis Lecturer for the present year, and had commenced a course of ten lectures on "Reptiles, living and extinct." These lectures were a continuation of a series given last year in connection with the London Society for the Extension of University Teaching. The number of animals in the Society's collection on the 31st of December last was 2525, of which 735 were mammals, 1331 birds, and 459 reptiles. Amongst the additions made during the past year, 13 were specially commented upon as of remarkable interest, and in most cases representing species new to the Society's collection. About 29 species of mammals, 21 of birds, and 3 of reptiles, had bred in the Society's Gardens during the summer of 1887. The Report concluded with a long list of the donors and their various donations to the Menagerie during the past year.—A vote of thanks to the Council for their Report was then moved by Dr. David Sharp, seconded by Mr. Robert McLachlan, and carried unanimously.—The Report having been adopted, the meeting proceeded to elect the new Members of Council and the Officers for the ensuing year. The usual ballot having been taken, it was announced that Dr. John Anderson, F.R.S., F. Du Cane Godman, F.R.S., John W. Hulke, F.R.S., Osbert Salvin, F.R.S., and Lord Walsingham, F.R.S., had been elected into the Council in place of the retiring members, and that Prof. Flower, C.B., F.R.S., had been re-elected President, Mr. Charles Drummond, Treasurer, and Dr. Philip Lutley Sclater, F.R.S., Secretary to the Society, for the ensuing year.—The meeting terminated with the usual vote of thanks to the Chairman, proposed by Lord Arthur Russell, seconded by Prof. G. B. Howes, and carried unanimously.

Mineralogical Society, May 8.—Prof. Bonney, F.R.S., Treasurer, in the chair.—The following papers were read:—Notes on some minerals from the Lizard, by Mr. J. J. H. Teall.—Contributions to the study of pyrargyrite and proustite, with analyses by Mr. G. T. Prior, by Mr. H. A. Miers.—On Cornish dufrenite, by Prof. E. Kinch.—On a peculiar variety of hornblende from Mynydd Mawr, Carnarvonshire; on a picrite from the Clicker Tor District, by Prof. T. G. Bonney, F.R.S.

PARIS.

Academy of Sciences, May 7.—M. Janssen, President, in the chair.—Note on the introduction of the element of mean averages in the interpretation of the results of statistical returns, by M. J. Bertrand. A demonstration is offered of the following theorem: Whatever be the number of urns (ballot-boxes and the like) and their composition, the law of discrepancies is the same for a single urn of given composition; but this urn will not yield the desired mean average. Hence in order to compare the results of statistical returns with those of abstract calculation two different urns must be assumed, the mean results being assimilated to the drawings made from the first, and the discrepancies to the results yielded by the second.—New theory of the equatorial *coudé* (continued), by MM. Lœwy and Puiseux. In this paper an explanation is given of the special processes applicable to the equatorial region, and of the physical methods employed to estimate the flexion of the axes. In a final paper the results will be given which have already been obtained in the application of this theory to the equatorial *coudé* of the Paris Observatory.—On the convergence of a continuous algebraic fraction, by M. Halphen. Three years ago the author communicated to the Academy the results of his researches concerning continuous fractions, which serve to develop the square root of a polynome of the third degree. In the present paper he extends his investigations to the case of a continuous fraction obtained by developing the function $f(x) = \frac{\sqrt{F(y)} - \sqrt{F(x)}}{y - x}$, where F indicates a polynome of the fourth or of the third degree.—On M. Massieu's characteristic functions in thermodynamics, by M. H. Le Chatelier. It is shown that these functions may be presented under a form somewhat different from that which they are usually made to assume, but which is more convenient for practical purposes.—On the variation of the specific heat of quartz with the temperature, by M. Pionchon. From the experiments the results of which are here tabulated it appears that from about 400° to 1200° C. the specific heat of quartz is constant and equal to 0·305. Thus the increase in the specific heat of this mineral is entirely confined to the interval between 0° and 400° C., a result which presents several points of interest in connection with M. Joubert's researches on the optical properties of the same substance.—On the theory of diamagnetism, by M. R. Blondlot. The author's experiments tend completely to confirm M. Ed. Becquerel's views regarding the mutual relations of paramagnetic and diamagnetic bodies. It is shown that these views are in no way affected by Tyndall's experiment, which fails to prove the existence of diamagnetic polarity, and which is perfectly explicable by Becquerel's theory.—On the electric phenomena produced by the ultra-violet rays, by M. Auguste Righi. In connection with M. Stoletow's recent communication on this subject, the author points out that several of the results here given were previously announced by him in a note presented to the Academy dei Lincei on March 4, and printed at the time.—On the acid phosphites of the alkaline metals, by M. L. Amat. To the acid phosphite of ammonia $(PO_3HO)NH_4O,HO$, previously prepared by him, the author here adds the corresponding salts of potassa and soda $(PO_3HO)KO,HO$ and $(PO_3HO)NaO,HO$, and explains their method of preparation.—On the crystalline form of the trithionate of soda, by M. A. Villiers. The author has succeeded in obtaining crystals of this substance, the measurements of which are here given.—On terpinol, by MM. G. Bouchardat and R. Voiry. It is shown that certain derivatives of the terebenthenes generally supposed to be identical with List's terpinol are really of different composition, although presenting some marked analogies with that substance.—M. G. Demeny describes a number of instruments which he has devised for the purpose of accurately determining the exterior form of the thorax, the extent of the respiratory movements, the profiles and sections of the trunk, and the volume of air inhaled and exhaled. The last-mentioned is described as a self-registering "spirometer."

BERLIN.

Physical Society, April 20.—Prof. du Bois-Reymond, President, in the chair.—Prof. Vogel communicated the results of his researches on the spectrum of carbon. In recent times the spectra of all the carbon compounds have been recognized as being those due to carbon itself, the sole exception being in the case of cyanogen, whose spectrum was considered to be that of the compound, not of carbon itself. The speaker had therefrom investigated the spectrum of cyanogen, with the help of photography. He obtained a spectrum which was marked, from the red to the ultra-violet, by very characteristic lines. The spectrum of a Bunsen burner was next photographed, and it was found that its first three lines coincide in all respects with those of the spectrum of cyanogen; in addition a series of lines lying between the above and also in the blue were found to be identical in both spectra. On the other hand, the two bands in the blue and ultra-violet were absent in the spectrum of the compounds of carbon and hydrogen, being replaced by a series of very characteristic double lines. Prof. Vogel next photographed the spectrum of carbonic oxide, and found that its more highly refracted portion corresponded completely with that of cyanogen. The bands in the blue and ultra-violet were particularly well marked, whereas the less highly refracted half of this spectrum did not correspond with that of cyanogen. Finally, the light emitted by the electric arc was photographed, and its spectrum resembled in all respects that of cyanogen. The speaker drew the conclusion from these observations that in all four cases he was really dealing with the spectrum of carbon. The differences in the several spectra are not dependent upon differences of temperature, inasmuch as the temperature of a Bunsen flame is higher than that of cyanogen, and notwithstanding this the latter gave a more highly developed and complicated spectrum. The speaker was much more inclined to assume the existence of modifications of carbon, of which one yields its spectrum in the Bunsen flame, the other in the flame of carbon monoxide, the two spectra being met with united in those of cyanogen and the electric arc respectively. In photographs of the solar spectrum, the dark background on which the line G is conspicuous shows such a marked correspondence with narrow bands in all the above four spectra that the existence of carbon in the sun must necessarily be assumed.—Prof. Vogel then spoke on colour-perceptions, which he explained by means of experiments. It is well known that when a colour-chart is seen illuminated by the light of a sodium flame it appears colourless: the yellow appears to be pure white, and the other colours appear gray, graduating into black. This result is not observed with other monochromatic light, such as that of thallium or strontium. The speaker was, however, able to produce the same result by means of coloured glasses, whether red, green, or blue; those colours always appeared to be white or very bright which most strongly reflected the light with which the colour-chart was illuminated, all the other colours appearing to be either gray or black. When a second monochromatic light was added to a previous one, such as blue to a yellow light, then definite colour-sensations were observed, which increased in number when a third source of monochromatic light was superadded to the other two. Prof. Vogel laid great stress on the perception of white by monochromatic illumination of a uniformly coloured field of view. He was not prepared to give any explanation of the phenomena, but simply to bring them to notice, with the intention of investigating them further.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

Nature's Hygiene, 3rd edition: C. T. Kingzett (Baillière, Tindall, and Cox).—Œuvres Complètes de Christiaan Huygens: Tome Premier, Correspondance 1638–56 (Nijhoff, La Haye).—Longmans' Junior School Geography: G. G. Chisholm (Longmans).—Kurzes Handbuch der Kohlenhydrate: Dr. B. Tollens (Trewendt, Breslau).—Geology for All: J. L. Lobley (Roper and Drowley).—The Elements of Logarithms: W. THURSDAY, MAY 24, 1888.

THE POLYTECHNIC INSTITUTE.

EVERY middle-aged inhabitant of the British Islands must recall more than one occasion when the mind of our country has been strongly stirred on the question of national defence. The adverse evidence of an expert, a rousing article in a newspaper, has often awakened general anxiety of more or less continuance, and followed by more or less adequate results. But it is far more difficult to awaken any widespread concern on behalf of those great abiding national interests which it is our charge and heritage to defend. And yet there are signs of no uncertainty which must to all thoughtful and instructed minds, from many directions, suggest the question whether that industrial leadership which has hitherto made our small and crowded country the world's workshop, and almost the world's mart, is not slipping from us. This is a question not of more or less wealth or luxury, but of very livelihood to the masses of the people under the special conditions of our national existence. If work ceases to come to a workshop, there is nothing for it but prompt dispersal of the workmen. All authorities seem agreed that the population of five or six millions inhabiting England and Wales in the time of Queen Elizabeth represents pretty nearly what their areas can sustain as agricultural, self-supporting countries. But the population of England and Wales alone was shown by the census of 1881 to have reached nearly twenty-six millions. So that seven years ago there was in the southern half of Great Britain an excess of twenty millions above what the country could reasonably support, except as a community of artificers and traders, and general carriers, by import and export, of the world's merchandise. It needs only a glance into past history to see that this, while an enviable position for a nation while prosperity lasts, is practical extinction when the channels of commerce are turned, or lost advantages have transferred production to new centres. Macaulay's fancy picture of the New Zealander sketching the ruins of St. Paul's from the broken arches of London Bridge seems of very little concern to the present citizen, whose ears are deafened with the ceaseless roar and traffic of the streets. And yet precisely that doom of silence and decay has befallen many a proud mother-city of which now "even the ruins have perished." It would far exceed present limits to show in detail how many articles of our own immemorial production we ourselves now largely import, because the foreign workman produces them better, or produces them at less cost. The evidence will be fresh in the recollection of the readers of this journal. Neither can they fail to recall with what persistence we have pointed out the remedy. There is but one real remedy: the better training of the workman; and—if we may be allowed to say it—of his employer too. Everyone who, without prejudice, has opportunity to watch a fair specimen of the British workman at his work must admit that the raw material is as good as ever it was; that in the quantity and quality of the work he can turn out in a given time, few of any nationality can equal, and none surpass him. But in the training he receives, and in the opportunities of his receiving it, there is much left to be desired. And, meantime, there is not only the grave fear, but, in many branches of industry, the accomplished fact, that other nations may and do outstrip us in the race.

Perhaps there is some belated merit in seeing that now; but all honour to those who, with heart and means to labour towards the better training of our artisans, devoted themselves to the endeavour when the need for it was less comparatively obvious. Honour especially to one man, Mr. Quintin Hogg, who, close upon a quarter of a century ago, at an age when most young men are concentrating their best energies on cricket, or football, or lawn tennis (all good things in their way), made it his life's task to raise the skilled workman of London, and furnish him more fully for his labour, for his own sake and for ours. Probably most of our readers know how that small enterprise has become a great one indeed, with the old Polytechnic for its present home and centre, and with a fuller variety of classes and branches, and with a greater comprehensiveness of scheme, than we can now attempt to describe. But all has hitherto rested on the shoulders, and been sustained by the purse, of Mr. Hogg himself, who, during the past six years, has spent, speaking broadly, some £100,000 in establishing and sustaining these admirable schools. But the time has now come when so great a burden, for the work's sake as well as for his own, should no longer depend upon the means and life of a single man; and there is now an opportunity of securing for the Institute something like an adequate endowment. The Charity Commissioners have offered to endow it with £2500 per annum on condition that the public find £35,000 as a supplementary fund. £18,000 have already been promised by the personal friends of the founder; but £17,000 still remain to be raised—a large sum no doubt, but a small one compared to our still unrivalled resources, and the national value of the Institute, not only for its own immediate results, but as a model for similar efforts in all the great centres of our industry. Those who believe in science—that is, in faithfully accurate and exact knowledge—as the only sure basis for any national prosperity that is to bear the stress of the fierce competition of our times, are earnestly invited to make themselves acquainted with the work of the Institute, and to contribute to its funds. Eighty-one thousand members and students have joined since it was moved to the Polytechnic, 309 Regent Street, in 1882. All donations or subscriptions will be thankfully received there, or by Mr. Quintin Hogg, 3 Cavendish Square, W.

THE GEOGRAPHICAL DISTRIBUTION OF THE FAMILY CHARADRIIDÆ.

The Geographical Distribution of the Family Charadriidæ; or the Plovers, Sandpipers, Snipes, and their Allies. By Henry Seebohm. (London: H, Sotheran and Co., 1888.)

THIS is a handsome volume of more than 500 pages, and it is illustrated by twenty-one coloured plates, drawn in Mr. Keuleman's best style. Mr. Seebohm has eschewed giving much information as to the habits of these families of wading birds, and has made a special point of the geographical distribution, a branch of the subject which cannot fail to attract the interest of every true naturalist. The introductory chapters treat of (1) the "Classification," and (2) the "Evolution" of Birds. Chapter III. details the author's views on the "Differentiation of Species," and Chapter IV. deals with the "Glacial Epoch." Chapters V. to IX. are devoted to the migration of birds, and end with a scheme of classification of the *Charadriidæ*. Here are, in fact, enunciated clearly all the articles of the Seebohm faith!

Evolutionists will probably join issue with Mr. Seebohm on many of his conclusions, and geologists may have something to say as to the possibility of glacial epochs causing all that the author claims for them, but ornithologists are scarcely likely to accept all his conclusions at once. If we are to believe Mr. Seebohm, there is very little progress being made in ornithological work in the Old World, his sympathies being evidently more with the American school of ornithologists, for whose method of nomenclature he has great respect. The non-adoption of trinomial principles Mr. Seebohm attributes to the "conservative views of British ornithologists," though he is mindful to add: "It is, however, only fair to remember that much allowance must be made for the narrow, because insular, views of British ornithologists." Shade of Darwin! The author has singled out the present writer as one of those who seem to have had "no definite idea of what they meant by a sub-species"; but we may assure Mr. Seebohm that in 1874 we did *not* use the term of *Gyps hispaniolensis* as a sub-species of *G. fulvus* "in an absolutely arbitrary manner," and we did not expect to find our nomenclature discussed under the heading of a "vague use of trinomials." Our object was to recognize evident facts, but at the same time to retain a binomial form of name for every bird, and the uncertainty which still surrounds the American method of trinomial names has not yet encouraged us to abandon the simpler and decidedly less clumsy way of expression. Surely Mr. Seebohm himself must admit that to have to speak of an Oyster-catcher as *Hæmatopus niger ater* (p. 311) is not an advantage, and this is only one result of pushing trinomial nomenclature to its extreme. There are not wanting signs that the advocates of the system are beginning to groan under the weight of the burden they have placed on their own shoulders; and when the inevitable return to the old simple path of binomial nomenclature takes place, the only tangible result will have been to have weighted the already frightful list of ornithological synonyms with an additional number of long names. Even Mr. Seebohm tries to modify the task of quotation of books by simplifying some titles; as, for instance, when he speaks of "Coues and Co., Check-List" (p. 427), as if the authors of the admirable A.O.U. "Check-List of North American Birds" had formed themselves into a Limited Liability Company for the manufacture of trinomials.

Another point on which Mr. Seebohm may fairly be called to task is for the number of new names which his book propounds. On the back of the title-page he quotes wise saws from the writings of John Ray (1878), A. R. Wallace (1876), and Henry Seebohm (1883), concerning the necessity of having simple names for birds, and those generally understanded of the people. Here are his own words:—"I have adopted a scheme which appears to me to be the most practical method of any which have been suggested. It may not satisfy the requirements of poetical justice; but it is at least consistent with common-sense. I adopt the name which has been *most used* by previous writers. It is not necessary for me to encumber my nomenclature with a third name, either to denote the species to which it refers, or to flatter the vanity of the author who described it: all my names are *auctorum plurimorum*." Either our author had forgotten that he had nailed this flag to the mast when he began the present book, or the system of *auctorum plurimorum* does not suit the *Charadriidæ*; for the next student of these birds will find that for the 235 species enumerated by Mr. Seebohm, he is responsible for giving to sixty-five of them names not previously in vogue; and the number would have been greater, had not Schlegel worked somewhat on the same line of ideas, while many of the trinomial combinations had been anticipated by "Coues and Co."

The book is profusely illustrated by woodcuts, showing the specific characters of the different species, and these will be invaluable to the student of these difficult birds. In fact, no work has ever been so remarkably treated in this respect, and it will be the book of reference for the *Charadriidæ* for many years to come. The "Keys to the Species" are also excellent, and Mr. Seebohm deserves every credit for having given us such a complete arrangement of some of the most tiresome of all the birds which it falls to the lot of the ornithologist to determine. Every naturalist who works out his facts as completely as the author has done is permitted to account for them by any theory which seems to him good; and Mr. Seebohm's arguments as to the origin of the species and their distribution are not only examples of clever writing, but are plausible enough if once the absolute certainty of the *Charadriidæ* having been driven from the Polar Basin by successive glacial epochs is conceded. Many ornithologists, however, will think that he carries his theory a little too far, as, for instance, when he places the Avocets and Stilts in one genus, *Himantopus*. How they originally came from the north, were split up in bands, became some of them "semi-Stilts" and "semi-Avocets"; how they thought nothing of emigrating (cause not hinted at) from the New World across the Atlantic to the Canary Islands and Spain, or from the Chilian sub-region across the Pacific to New Zealand and Australia—these and many other interesting theories of distribution will reward the student of Mr. Seebohm's book. Most ornithologists will be more grateful for small mercies than Mr. Seebohm is, and thank Dame Nature for having given them characters whereby in a few lines a genus can be written down. Take, for instance, the members of the genus *Esacus*, which Mr. Seebohm unites to *Œdicnemus*, and yet his woodcuts show that the former genus has an enormous bill, longer than the head itself—surely a genuine character of importance. Then, again, *Anarhynchus*, with its asymmetrical bill—confined to New Zealand—need not be united to *Charadrius*;—and so on. With his theory of distribution strong in his mind, the Avocets, with up-turned bill, are united to the Stilts, with their straight bill, because Mr. Seebohm has no doubts as to their common origin in the distant past; but looking at the present almost identical distribution of *Himantopus melanopterus* and *Recurvirostra avocetta*, *H. mexicanus* and *R. americana*, it would seem as if they had long ago been separated as distinct generic forms, as they would have no business to occupy the same areas, if Mr. Seebohm's theory were true. Is it not possible that they were developed as Avocets and Stilts in very remote times, and that similar causes have driven them to occupy the same areas of distribution? And may not both have had a *southern* instead of a northern origin? Thus *Cladorhynchus* in Australia, *Himantopus andinus* in the Andes (apparently, from Mr. Seebohm's illustration, belonging to a distinct genus), and the various species of Stilts in Australia, New Zealand, and Brazil, would remain as isolated species of a former stock, which probably inhabited a continuous area in the South Atlantic and South Pacific Oceans. Where circumstances were favourable to their stay, some may not have migrated northwards, and the differences in some of the southern species could be accounted for by their subsequent isolation, rather than by their inconsequent flight from Chili to New Zealand, as Mr. Seebohm supposes.

Besides the woodcuts of heads, tails, &c., and other specific characters, the present volume is crowded with woodcut illustrations by Mr. John Millais, Mr. Lodge, and Mr. Holding. They are mostly extremely well done, but Mr. Millais seems a little inclined to fashion his Waders on the model of a peg-top.

R. Bowdler Sharpe.

THE MINERALS OF NEW SOUTH WALES.

The Minerals of New South Wales, &c. By A. Liversidge, M.A., F.R.S., Professor of Chemistry and Mineralogy in the University of Sydney. (London: Trübner and Co., Ludgate Hill, 1888)

IT was a very happy thought of Prof. Liversidge to celebrate the centenary of the foundation of the colony of New South Wales by the publication of this handsome and comprehensive volume. Giving, as it does, a very clear account of what is known of the mineral resources of the oldest of the Australian colonies, it brings clearly before the mind of the reader how much has already been accomplished in developing the subterranean resources of an important part of the British Empire, and how large is the promise for the future. The term "mineral," we may mention, is not employed in this work in its narrower scientific sense; coals and oil-shales, and even mineral waters, receiving a due amount of notice in it.

The basis of the present work is found in a paper published by the author in the Transactions of the Royal Society of New South Wales, in 1874, of which memoir a second edition was published by the Mining Department of the colony in 1882. Prof. Liversidge has added very largely to his original memoir; and the numerous analyses of minerals and rocks, made by himself, Mr. W. J. Dixon, F.I.C., and the Government Analyst of the Mining Department, greatly increase the value of the book. Owing to the absence of the author from the colony during the past year, the work has been printed and issued in this country; but, as a proof of the manner in which the book has been brought fully up to date, we may note the statement, on p. 185, of the discovery, by Mr. T. W. Edgworth David, of the Geological Survey of New South Wales, of the sparsely distributed mineral leucite in the Australian colony, the fact having only been announced to the Mineralogical Society so recently as October in last year.

A considerable amount of space is naturally devoted to discussions concerning the occurrence of the precious metals—the account of gold occupying 34 pages, and that of silver 13 pages. The interesting series of assays of New South Wales gold, and an account of the chief nuggets found in the colony, are of much interest. In connection with this subject, we have in the work before us a very clear and concise, but very carefully drawn up, statement concerning the often-disputed question of the original discoverer of gold in Australia. The author states his facts and sources of information, taking great care to give references in all cases, and those interested in the question will have little difficulty in arriving at a decision as to the relative merits of the claims which have been put forward on behalf of Count Strzelecki, the Rev. W. B. Clarke, Sir Roderick Murchison, and other less known individuals, to whom the discovery has been ascribed. One of the most interesting and instructive among the many tabular statements in this work is that which indicates the number of minerals which have yielded, on assay, larger or smaller quantities of gold and silver. This table seems to indicate that, even should the alluvial washings and quartz-reefs be exhausted of their auriferous contents, there still remain in Australia many available and very valuable sources of the precious metals.

Still more important in its bearing on the future welfare of the colony is the account of the common metallic ores, and of the coal, lignite, and oil-shale deposits. There are few, if any, of the metals used in the arts, of which abundant sources of supply are not found within the limits of the colony. The coal-fields are said to cover about one-half the area of those of Great Britain, and numerous analyses and other details enable us to judge of the quality of the fuels which they yield. In the discussion of this important question, Prof. Liversidge's great knowledge and experience as a chemist invest his opinions with the highest value.

Although the book is not a technical mineralogical treatise alone, mineralogists will find very careful descriptions of all the minerals, including the gem stones, which have been found within the colony. Their study of the subject will be much facilitated by the large coloured map which forms a frontispiece to the volume.

In concluding this notice we cannot but congratulate the author upon the enterprise and energy which have enabled him to prepare such a treatise as the present one. The objects aimed at in such books as Zepharovic's "Mineralogisches Lexicon für das Kaiserthum Oesterreich" may seem at first sight incompatible with those to which works like Mr. Albert Williams's "Mineral Resources of the United States" are devoted; but Prof. Liversidge has shown that this is by no means the case, and he has achieved the feat in the case of a young and rising colony, where the difficulties of the undertaking must have been more than usually great. The colony, too, is to be congratulated on its good fortune in having as an occupant of the Chemical Chair in its University, one who has shown himself so successful in attaining practical, while not losing sight of the scientific, results of his researches.

OUR BOOK SHELF.

Elementary Chemistry. By William S. Furneaux, F.R.G.S., Science Demonstrator, London School Board. (London: Longmans, Green, and Co., 1888.)

THE main object of this little work is to assist young students intending to sit for the chemistry examination of the Science and Art Department in the new alternative elementary stage. It appears to be, in fact, an illustrated expansion of the detailed syllabus published by the Department in their Directory.

The want of such a work has possibly been felt by many teachers of this "alternative" or "natural" chemistry, which appears to be rapidly becoming more and more popular with young beginners. There is something truly fascinating in learning these mysteries of common things, and, what is still more important, the knowledge gained has its practical applications in every-day life. In order to afford teachers some idea of the methods recommended of performing the class experiments themselves, the Department have caused to be placed in the western galleries of the South Kensington Museum a complete set of apparatus, as simple and inexpensive as is compatible with the object in view, arranged under the personal direction of the examiners, to illustrate the method of performing each of the experiments indicated in the syllabus. It is to be hoped, therefore, that all who are interested in the teaching of the alternative elementary stage of chemistry, and who can conveniently do so, will avail themselves of this opportunity of comparing the experimental methods there recommended with those which they themselves have previously adopted. One cannot help thinking that many of the methods illustrated by Mr. Furneaux are much too complicated, and it is to be regretted that his book was in the press before the completion of the collection in the western galleries, which was accomplished about two months ago.

The majority of the theoretical explanations leave little to be desired. The ideas of the author, however, as to the nature of the Bunsen flame appear scarcely to accord with more recent investigations, the effect of mixture with an inert gas being entirely overlooked. A. E. T.

Companion to the Weekly Problem Papers. By the Rev. John Milne, M.A. (London: Macmillan and Co 1888.)

THE title of this work gives no adequate idea of its contents. It consists of some 340 pages, which, if about 60 pages be excepted, are devoted entirely to geometry. Besides the author, several other mathematicians are contributors, viz. Mr. R. F. Davis, Prof. Genese, Rev. T. C. Simmons, and Mr. E. M. Langley.

The object of the book seems to be to give prominence to what is here designated "The Modern Geometry of the Triangle." This is seen to consist of a group of pretty theorems which arise from a consideration of the "Brocard points" and the "Lemoine point" of a triangle. The successive chapters bear the titles, "Antiparallels, Isogonals, and Inverse Points," "The Brocard Points and Brocard Ellipse," "The Lemoine Point and Triplicate Ratio Circle," "The Brocard Circle and First Brocard Triangle," "The Tucker Circles," "The Cosine and Taylor Circles," "The Co-Symmedian and Co-Brocardal Triangles," and "Miscellaneous Theorems and Constructions." They comprise a good and almost complete account of the present knowledge of these subjects.

On p. 180 there is a *résumé* of the bibliography, which has evidently been carefully compiled by the knot of enthusiasts in this country who have followed in the footsteps of M. Lemoine M. Brocard, M. Vigarié, Prof Neuberg, M. Catalan, and others. To these investigators on the Continent most of the results here given were known prior to 1881; they were subsequently arrived at independently by mathematicians in England who were unacquainted with the work already accomplished, in the same field of research, abroad. In fact, in the *résumé*, discoveries, and rediscoveries, and rediscoveries of rediscoveries succeed one another in bewildering fashion. The reasons which have led to the nomenclature in certain cases are difficult to fathom. We find, for instance, a circle associated with the name of one mathematician, when, admittedly, the same circle had been examined by a Continental investigator some years previously, whose name, if name be necessary, it ought to bear.

The algebraic portions comprehend sections on "Theory of Maximum and Minimum," "Theory of Elimination," "Summation of Series," "Binomial Series," and "Algebraical and Trigonometrical Identities."

The book will be chiefly useful to those who take an interest in recent triangular geometry; it will enable them to refer to original sources in Continental mathematical publications, and to follow further developments in English magazines. They will also find collected here most of the leading propositions given in a form which is without doubt both judicious and attractive.

Elementary Hydrostatics, with Numerous Examples and University Papers. By S. B. Mukerjee, M.A. (Calcutta: Thacker, Spink, and Co., 1888.)

THE compiler of this handy little work is Assistant Professor of Mathematics in the Lahore College, who, having been, as is the wont of his order, unable to select from the numerous text-books in existence one which seemed fully to meet the wants of his classes, has culled his elegant extracts from them, and so got what he wanted. This proceeding is a good one for his pupils, and saves them the trouble and expense of purchasing and reading many text-books. The selection is well made, and the compiler suitably acknowledges his indebtedness to the English writers (especially to Dr. Besant's classical work). The subjects handled are definitions and first principles, density and specific gravity, equilibrium of fluids, total pressures and resultant pressures on immersed surfaces, floating bodies, on air and gases, determination of specific gravities, and the application of hydrostatical principles in the construction of instruments and machines. Then follow several papers of problems set in the Calcutta University Examinations from 1860 to 1884; and the book closes with an appendix of formulæ to be remembered, and another appendix which gives a short history of the growth of the principles of hydrostatics, taken for the most part from Whewell's "History of the Inductive Sciences." In the body of the work are given numerous illustrative examples, many of which have been carefully worked out. Putting on one side the manufacture of the book—and herein, perhaps, Mr. Mukerjee is only more honest in making known his indebtedness than many are in the writing of text-books—we can congratulate the students on having such a good work in their hands, and can indorse the favourable opinion expressed upon it by Prof. T. C. Lewis, Principal of the College.

Arithmetic for Beginners: a School Class-book of Commercial Arithmetic. By the Rev. J. B. Lock, M.A. (London: Macmillan and Co., 1888.)

IT is not necessary to report upon this little book at any length. It is founded upon the author's larger work, but modifications as to arrangement and treatment of some of the subjects and as to the examples have been introduced. Then, with an eye to the requirements of the examination for commercial certificates, a chapter on exchange and foreign money has been added (in a worked-out example on p. 151 there is an error of some pecuniary magnitude), and the chapter "On Recurring Decimals, not required by Commercials," finds a place at the close of the text. Mr. Lock is generally so careful in his explanations that we are surprised at his omitting all reference to brokerage in his account of the transferment of stock. Numerous examples are given in the text, and six examination-papers and answers to all questions complete a capital hand-book.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Weight and Mass.

PROF. GREENHILL, in his letter which appears in NATURE of May 17 last (p. 54), has again repeated his views on the use of the word *weight*. He has not, however, replied to the criticisms of those who differ from him (see NATURE, vol. xxxvi. pp. 221, 317).

His opponents wish to know how practical engineers who use the word *weight* as synonymous with the physicists' mass, treat a problem involving inertia. Prof. Greenhill has not yet given us an example of such a problem taken from some modern text-book of the practical engineer; nor has he yet given us in simple language a definition of weight. Prof. Greenhill some time ago referred me to Kennedy's "Mechanics of Machinery" for such a definition, but I venture to say that there is no such definition to be found in that standard work.

My own idea is as follows: Matter has many properties—inertia, weight (the force with which the earth pulls it), volume, &c.—and Newton's great discovery consisted partly in seeing clearly that the universal property of matter by which it must be measured is its *inertia*, defined as its capacity for resisting change of velocity.

The *mass* of a body is that which can be ascertained by the operation of *massing;* such an operation, that is, as the following: To a given lump of matter apply some strain or force, and observe the acceleration produced in the matter by that force; then ascertain by experiment to how many lumps of matter called pounds this same force will communicate an equal acceleration.

The *weight* of a body is that which is ascertained by the operation of *weighing*. To weigh a body it is placed on a spring balance, and the force of the earth's attraction is observed by showing the compression of the steel spring of the machine.

It happens, however, that the mass of a body is proportional to its weight; consequently it is sufficient to ascertain whether the weights of two masses are equal in order to ascertain that their masses are equal. The weights of two masses are ascertained to be equal by putting them each on one side of a balance, and observing that the force of the earth's attraction on each is the same. Hence the very difficult operation of *massing* as described above is replaced by the easy operation of weighing.

Prof. Greenhill tells us that "now the invariable unit, the mass, is measured in terms of a variable unit." Is this so? Is it not a fact that those who use exclusively the force of the earth's attraction as the measure of matter, rarely if ever have any conception of the idea of inertia? When the practical engineer has to do with inertia, as in cases of "*centrifugal force,*" he works by formulæ or rule of thumb.

Prof. Greenhill's sentences, "a force equal to the weight of the mass of 10 pound weights," and "the weight of 32 pound weights on the Earth is at the surface of Jupiter a force of 71 pounds' weight," are entirely original.

I believe he means to express "the weight of 10 pounds," and the weight of 32 pounds on the earth is a force equal to the weight of 71 pounds on the surface of Jupiter.

Caius College, May 21. JOHN B. LOCK.

Work and Energy.

WHILE a discussion of the nomenclature of mechanics is going on in NATURE, I would venture to suggest that an effort should be made to get rid of the practice of expressing energy in foot-pounds or foot-poundals. There are certain quantities of work, not of energy. To speak of a foot-pound of energy is quite as incorrect as it would be to speak of a pint of velocity, a yard of acceleration, an acre of momentum, or a pound of duration. There is great need of a short name for the unit of $\frac{1}{2}mv^2$.

Bardsea, May 21. EDWARD GEOGHEGAN.

On the Reappearance of Pallas's Sand Grouse (*Syrrhaptes paradoxus*) in Europe.

I BEG to add the following statements to my communication of May 12 concerning Pallas's sand grouse in Central Europe (see NATURE, May 17, p. 53):—

April 22, Cernozitz, Bohemia.
,, 26, Portitz, near Leipzig, Saxony.
,, 27, Güttmannsdorf, near Reichenbach, Silesia.
,, 27? near Hanover.
,, 27-28, near Hermannstadt, Transylvania.
,, 29, Marmarosch-Comitate, Hungary.
Last days of April: Alsofehér-Comitate, Transylvania.
Gebhardsdorf, Silesia.
Brod, Bohemia.
First days of May: Tullner-field, near Vienna.
Moravia.
Hungary.
Enzersdorf, near Vienna.
Anclam, Pomerania, Prussia.
May 6, Haida, Bohemia.
,, 6, Eidelstedt, near Hamburg.
,, 7? near Schweinitz, Silesia.
,, 7, Oederan, Saxony.
,, 7, 6.30 a.m., near Oederan, Saxony.
,, 8, Wiener Neustadt, Austria.
,, 8? Dalmatia.
,, 8? Grossvoigtsberg, Saxony.
,, 8? near Leipzig, Saxony.
,, 8? near Herrenhut, Saxony.
,, 9, Oederan, Saxony, and nearly every following day there.
,, 13, Selb, Saxony.
,, 13? Grossvoigtsberg, Saxony.
,, 13, Schluckenau, Bohemia.
,, 16, 5 p.m. Oederan, Saxony.

A. B. MEYER.

Royal Zoological Museum, Dresden, May 20.

A FARM in this neighbourhood was visited yesterday by a flight of about forty sand-grouse (pin-tailed). They were first seen about 6 p.m. feeding on a ploughed field. On rising they took a north-westerly course. A pair which were shot by a gamekeeper are in my possession. The presence of these birds in our country is, I believe, of sufficiently rare occurrence to justify me in asking whether they have been noticed in other districts during the last few days. F. M. CAMPBELL.

Rose Hill, Hoddesdon, Herts, May 21.

Tables of Reciprocals.

IN investigating spectral phenomena it is often necessary to convert wave-lengths in frequencies. Can any of your correspondents inform me if there exist in England tables of reciprocals, by which this may be done easily and with sufficient accuracy? V. A. JULIUS.

Delft, Holland, May 19.

On the Veined Structure of the Mueller Glacier, New Zealand.

THE Mueller Glacier, in the Mount Cook district, has a total length of between six and seven miles, with a breadth of one mile in its lower portion. Like most, if not all, of the New Zealand glaciers of the first order, the lower mile or two is so thickly covered with rock debris that the ice can only be seen in the crevasses. All through the lower portion of the glacier the veined or ribboned structure is well marked, running nearly in the direction of the glacier. But at the terminal face there are two systems of veined structure, with the same strike but crossing one another at angles between 15° and 20°. In one system the blue bands are small, from a half to one inch thick, and separated from each other by bands of white ice, with large air-bubbles, about twice the thickness of the blue bands. The blue bands are irregular and sometimes anastomose. This system is similar to the veined structure found higher up the glacier.

The second system is formed by large and regular blue bands from three to six inches broad and from two to six or more feet apart. This coarser system is only occasionally developed. The finer system forms a well-marked synclinal curve on the terminal ice cliffs, which are from 250 to 300 feet high.

The ice here contains in places numerous angular stones, principally of slate, scattered irregularly through it, and these fragments always have their broad, or cleaved, surfaces parallel to the smaller system of veins. These stones have no doubt entered the ice through the numerous moulins and crevasses which are found higher up the glacier, but as they are not found in bands nor in pipes, they must have been moved in position by the flowing of the ice, consequently they must originally have been variously oriented, and their present parallelism to the veins is a decisive proof that the smaller system is due to pressure at right angles to the structure. The origin of the coarser system is not so clear. I did not notice it higher up the glacier, as I ought to have done if it had been an older system than the smaller veins. While, on the other hand, if it is a newer system the rock fragments would probably have been oriented parallel with it instead of with the finer system.

The clear blue ice is generally supposed to resist melting better than the white ice, and to stand out in ridges; but I observed nothing of this on the Mueller Glacier. Both kinds of ice melt here with about equal rapidity. The grooving of the ice, by runlets of water, is certainly parallel to the structure when that structure is vertical or highly inclined; but the grooves are formed in several layers of both kinds of ice, and it seemed to me that the blue ice melted rather more rapidly than the white ice. I cannot suggest any cause for this difference between the ice of the Mueller Glacier and that of the Swiss glaciers. F. W. HUTTON.

Christchurch, New Zealand, March 22.

On the Rainfall and Temperature at Victoria Peak, Hong Kong.

THE first column of the following table shows the month of the year; the second, the mean rainfall at the Observatory (about 100 feet above the sea) from ten years' records; the third, the mean of the past four years' fall; the fourth, same for Victoria Peak (about 1800 feet above the sea); the fifth, the proportion between the figures in the two preceding columns; the sixth, the height of ascent in feet for one Fahrenheit degree of decrease of temperature (mean of the past four years):—

I.	II.	III.	IV.	V.	VI.
January	1·47	2·97	4·63	1·56	288
February	1·66	2·30	3·56	1·55	305
March	3·53	3·41	3·60	1·06	489
April	6·55	7·89	9·19	1·16	407
May	9·82	4·86	6·29	1·29	309
June	12·67	14·42	16·71	1·16	259
July	16·41	16·55	20·29	1·23	274
August	16·93	15·27	17·53	1·15	289
September	9·89	7·98	7·01	0·88	283
October	5·06	2·57	2·06	0·80	281
November	1·04	0·77	1·19	1·54	267
December	0·49	0·97	1·21	1·25	278
Year	85·52	79·96	93·27	1·17	310

The rainfall at the Peak exceeds the record at the Observatory by about one-sixth of the whole amount, and this appears to be due to the circumstance that the mountain presents an obstacle to the wind from whatever side it blows, in consequence of which the air is forced to rise, and being thereby cooled it precipitates more moisture in the form of rain. Even when the air is moderately dry at sea-level its temperature may be decreased below the dew-point in the course of such a rise. The comparatively great rainfall in hilly districts must be attributed to this, for a hill must of course exercise its influence at a distance all round. Our rainfall would therefore be smaller if there were no hills in this neighbourhood. But during the months of September and October less rain is collected at the upper level. This is explained by the circumstance that most of the rain in those months is due to typhoons, when the air is everywhere ascending, even above the open sea; and the defect at the Peak is most noticeable during the raging of a typhoon. The fact that less rain is measured above must, however, be further investigated. It is very doubtful whether it would not be as well to expose the funnels of the gauges 4 feet above the ground, where they would not be so much affected by the rain drifting along the surface of the earth in typhoons, as to have them 1 foot above the grass, as is the case here.

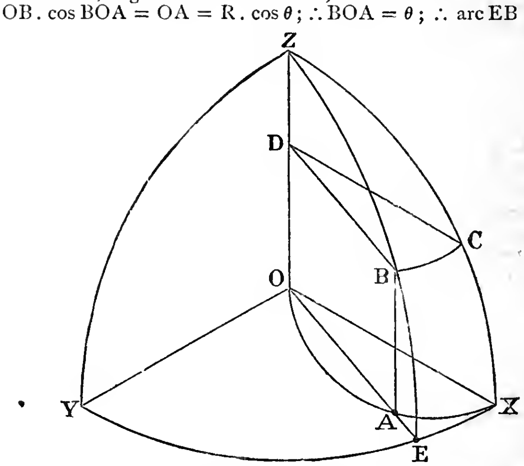
The last column of the table proves the great variability of the fall of temperature with increasing height. It depends upon the humidity of the air. The astronomical refraction near the horizon must be affected by this, but it is rather doubtful whether the effect should be ascertained by comparing observed refractions with meteorological registers kept on mountains on account of the condensation of moisture which tends to raise the temperature on the top of the hill. But it would appear to be time that some astronomer studied the refraction in connection with daily weather-maps, seeing that the variation of temperature with increasing height is so different in cyclones and anticyclones. Of course near the centre of a cyclone it is scarcely possible to make astronomical observations. Bessel's theory of refraction is considered a failure within 5° of the horizon. Ivory's theory might possibly be made to account for the refraction nearly down to the horizon by observing the value of the constant f in connection with the isobars. It, on the whole, represents the variation of temperature high up in the air as estimated by meteorologists. W. C. DOBERCK.

Hong Kong Observatory, February 11.

Problem by Vincentio Viviani.

To pierce in an hemispherical dome four windows such that the remainder of the surface shall be exactly quadrable. It was solved by Leibnitz, J. Bernoulli, and others. Viviani himself, in 1692, published the construction, but without proof. Divide the base of the dome into quadrants; on the four radii as diameters trace semi circles, one in each quadrant; the four right semi-cylinders, of which these are the bases, will pierce the dome in the required windows. The following simple proof, for which I am substantially indebted to Prof. Francis W. Newman, would probably interest many readers of NATURE:—

OXYZ is quarter of dome; AB, generator of cylinder meeting dome in B; BCD, plane parallel to base. Radius of dome $= R =$ OX = OB; angle CDB = XOA $= \theta$; DC = DB = OA $= R\cos\theta$; OB . cos BOA = OA = R . $\cos\theta$; ∴ BOA $= \theta$; ∴ arc EB $= R\theta$;



arc BC $= \theta \,.\, R\cos\theta$. Element of surface of window is BC . d(EB) $= R^2\theta \,.\, \cos \,.\, \theta \,.\, d\theta$; ∴ surface of window is the integral of this from $\theta = 0$ to $\theta = \frac{1}{2}\pi$. Integrating by parts, and taking limits, surface of window $= R^2\left(\frac{1}{2}\pi - 1\right)$; ∴ the remainder of the surface XYZ is R^2, which is exactly quadrable. Q.E.D.

Cor. The quadrable part of the quarter-dome is equal to the surface of the semi-cylinder which is within the dome. For, if AB $= z$, and arc XA $= s = R\theta$, element of surface of the cylinder is $z \,.\, ds = R^2 \,.\, \sin\theta \,.\, d\theta$; ∴ the entire surface within the dome is the integral of this from $\theta = 0$ to $\theta = \frac{1}{2}\pi$, viz. R^2.

A general discussion of Viviani's problem may be seen in Lacroix, "Traité du Calcul Differentiel et du Calcul Intégral," tome ii. pp. 219–22. EDWARD GEOGHEGAN.

Bardsea, May 2.

SUGGESTIONS ON THE CLASSIFICATION OF THE VARIOUS SPECIES OF HEAVENLY BODIES.[1]

VI.

ON THE CAUSE OF VARIATION IN THE LIGHT OF BODIES OF GROUPS I. AND II.

I. GENERAL VIEWS ON VARIABILITY.

IN my former paper I referred to the collision of meteor-swarms as producing "new stars," and to the periastron passage of one swarm through another as producing the more or less regular variability observed in the case of some stars of the class under consideration.

I propose now to consider this question of variability at somewhat greater length, but only that part of it which touches non-condensed swarms; *i.e.* I shall for the present leave the phenomena of new stars, and of those whose variability is caused by eclipses, aside.

It is not necessary that I should pause here to state at length the causes of stellar variability which have been suggested from time to time. It will suffice, perhaps, that I should refer to one of the first suggestions which we owe to Sir I. Newton, and to the last general discussion of the matter, which we owe to Zöllner ("Photometrische Untersuchungen," 76 and 77, p. 252).

Newton ascribed that special class of variability, to which I shall have most to refer in the sequel, as due to the appulse of comets.

"Sic etiam stellæ fixæ, quæ paulatim expirant in lucem et vapores, cometis in ipsas incidentibus refici possunt, et *novo alimento accensæ pro stellis novis haberi.* Hujus generis sunt stellæ fixæ, quæ subito apparent, et sub initio quam maxime splendent, et subinde paulatim evanescunt. Talis fuit stella in cathedra Cassiopeiæ quam Cornelius Gemma octavo Novembris 1572 lustrando illam cœli partem nocte serena minime vidit; at nocte proxima (Novem. 9) vidit fixis omnibus splendidiorem, et luce sua vix cedentem Veneri. Hanc Tycho Brahæus vidit undecimo ejusdem mensis ubi maxime splenduit; et ex eo tempore paulatim decrescentem et spatio mensium sexdecim evanescentem observavit" ("Principia," p. 525, Glasgow, 1871).

With regard to another class of variables he makes a suggestion which has generally been accepted since.

"Sed fixæ, quæ per vices apparent et evanescunt, quæque paulatim crescunt, et luce sua fixas tertiæ magnitudinis vix unquam superant, videntur esse generis alterius, et revolvendo partem lucidam et partem obscuram per vices ostendere. Vapores autem, qui ex sole et stellis fixis et caudis cometarum oriuntur, incidere possunt per gravitatem suam in atmosphæras planetarum et ibi condensari et converti in aquam et spiritus humidos, et subinde per lentum calorem in sales et sulphura et tincturas et limum et lutum et argillam et arenam et lapides et coralla et substantias alias terrestres paulatim migrare."

Zöllner, in point of fact advancing very little beyond the views advocated by Newton and Sir W. Herschel, considers the main causes of variability to be as follows. He lays the greatest stress upon an advanced stage of cooling, and the consequent formation of scoriæ which float about on the molten mass. Those formed at the poles are driven towards the equator by the centrifugal force, and by the increasing rapidity of rotation they are compelled to deviate from their course. These facts, and the meeting which takes place between the molten matter, flowing in an opposite direction, influence the form and position of the cold non-luminous matter, and hence vary the rotational effects, and therefore the luminous or non-luminous appearance of the body to distant observers.

This general theory, however, does not exclude other causes, such as, for instance, the sudden illumination of a star by the heat produced by a collision of two dark bodies, variability produced by the revolution of a dark body, or by the passage of the light through nebulous light-absorbing masses.

If the views I have put forward are true, the objects now under consideration are those in the heavens which are least condensed. In this point, then, they differ essentially from all true stars like the sun.

This fundamental difference of structure should be revealed in the phenomena of variability; that is to say, the variability of the bodies we are now considering should be different *in kind* as well as in degree from that observed in bodies like the sun or α Lyræ, taken as representing highly condensed types. There is also little doubt, I think, that future research will show that, when we get short-period variability in bodies like these, we are really dealing with the variability of a close companion.

II. ON THE VARIABILITY IN GROUP I.

That many of the nebulæ are variable is well known, though so far as I am aware there are no complete records of the spectroscopic result of the variability. But bearing in mind that in some of these bodies we have the olivine line by itself, and in others, which are usually brighter, we have the lines of hydrogen added, it does not seem unreasonable to suppose that any increase of temperature brought about by the increased number of collisions should add the lines of hydrogen to a nebula in which they were not previously visible.

The explanation of the hydrogen in the *variable* stars is not at first so obvious, but a little consideration will show that this must happen if my theory be true.

Since the stars with bright lines are, as I have attempted to show, very akin to nebulæ in their structure, we might, reasoning by analogy, suppose that any marked variability in their case also would be accompanied by the coming out of the bright hydrogen lines.

This is really exactly what happens both in β Lyræ and in γ Cassiopeiæ. In β Lyræ the appearance of the lines of hydrogen has a period of between six and seven days, and in γ Cassiopeiæ they appear from time to time, although the period has not yet been determined.

III. ON THE VARIABILITY IN GROUP II.

This same kind of variability takes place in stars with the bright flutings of carbon indicated in their spectra, *o* Ceti being a marvellous case in point. In α Orionis, one of the most highly-developed of these stars, the hydrogen lines are invisible; the simple and sufficient explanation of this being that, as I have already suggested, the bright lines from the interspaces now at their minimum and containing vapours at a very high temperature—*teste* the line-absorption spectrum now beginning to replace the flutings—balance the absorption of the meteoritic nuclei.

Anything which in this condition of light-equilibrium will increase the amount of incandescent gas and vapour in the interspaces will bring about the appearance of the hydrogen lines as bright ones. The thing above all things most capable of doing this in a most transcendental fashion is the invasion of one part of the swarm by another one moving with a high velocity. This is exactly what I postulate. The wonderful thing under these circumstances then would be that bright hydrogen should *not* add itself to the bright carbon, not only in bright-line stars, but in those the spectrum of which consists of mixed flutings, bright carbon representing the radiation.

[1] The Bakerian Lecture, delivered at the Royal Society on April 12, by J. Norman Lockyer, F.R.S. Continued from p. 60.

I now propose to use this question of variability in Group II. as a further test of my views.

The first test we have of the theory is that there should be more variability in this group than in any of the others. Others are as follows. (2) When the swarm is most spaced, we shall have the least results from collisions, but (3) when it is fairly condensed, the effect at periastron passage (if we take the simplest case of a

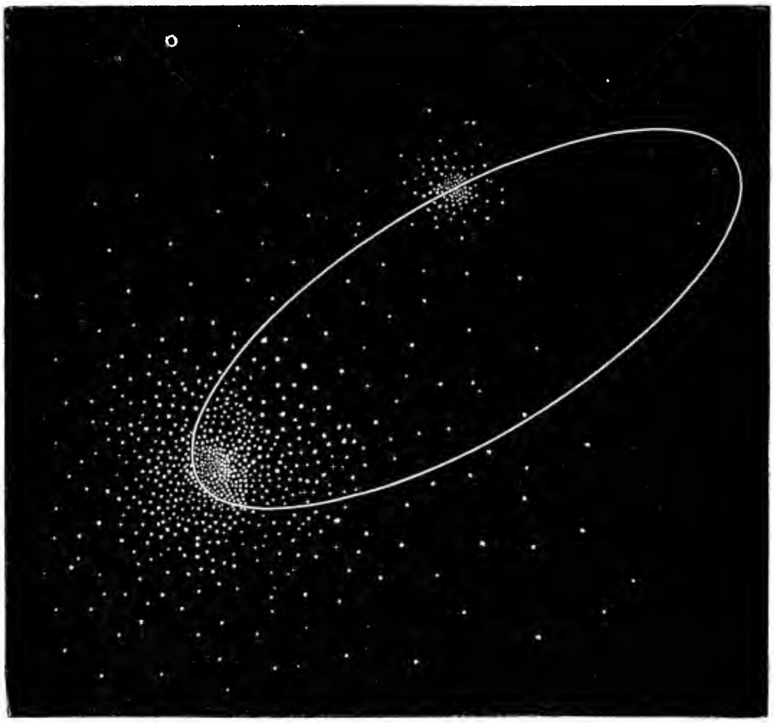


FIG. 11.—Explanation of the variability of bodies of Group II. (1) Maximum variation. The ellipse represents the orbit of the smaller swarm, which revolves round the larger. When the variation is great, the orbit of the revolving swarm is very elliptical, so that at periastron the number of collisions is enormously increased.

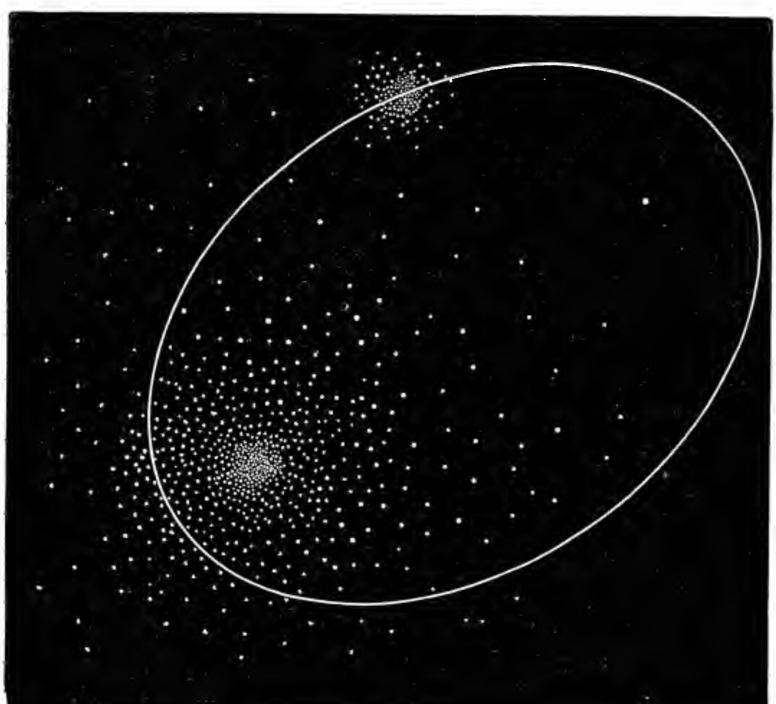

FIG. 12.—Explanation of the variability of bodies of Group II. (2) Medium variation. There will be a greater number of collisions at periastron than at other parts of the orbit, but the variation in the light will not be very great under the conditions represented, as the revolving swarm never gets very near the middle of the primary one.

double star *in posse*) will be greatest of all, because (4) condensation may ultimately bring the central swarm almost entirely within the orbit of the secondary (cometic) body, in which case no collision could happen.

In the light of what has gone before it is as easy to test these points as the former ones.

I will take them in order.

The Frequent Occurrence of Variability in Group II.

The total number of stars included in Argelander's Catalogue, which deals generally with stars down to the ninth magnitude, but in which, however, are many stars between the ninth and tenth, is 324,118. The most complete catalogue of variables (without distinction) that we have has been compiled by Mr. Gore, and published in the Proceedings of the Royal Irish Academy (series ii. vol. iv. No. 2, July 1884, pp. 150–63). I find 191 known variables are given, of which 111 are in the northern hemisphere and 80 in the southern hemisphere.

In the catalogue of *suspected* variable stars given in No. 3 of the same volume (January 1885, pp. 271–310), I find 736 stars, of which 381 are in the northern and 355 in the southern hemisphere.

Taking, then, those in the northern hemisphere, both known and suspected, we have the number 492.

We have then as a rough estimate for the northern heavens one variable to 659 stars taken generally.

The number of objects of Group II. observed by Dunér, and recorded in his admirable memoir, is 297 of these, forty-four are variable.

So that here we pass from 1 in 657 to 1 in 7.

Of the great development of variability-conditions in this group then there can be no question.

To apply the other tests above referred to, I have made a special study of the observations of each variable

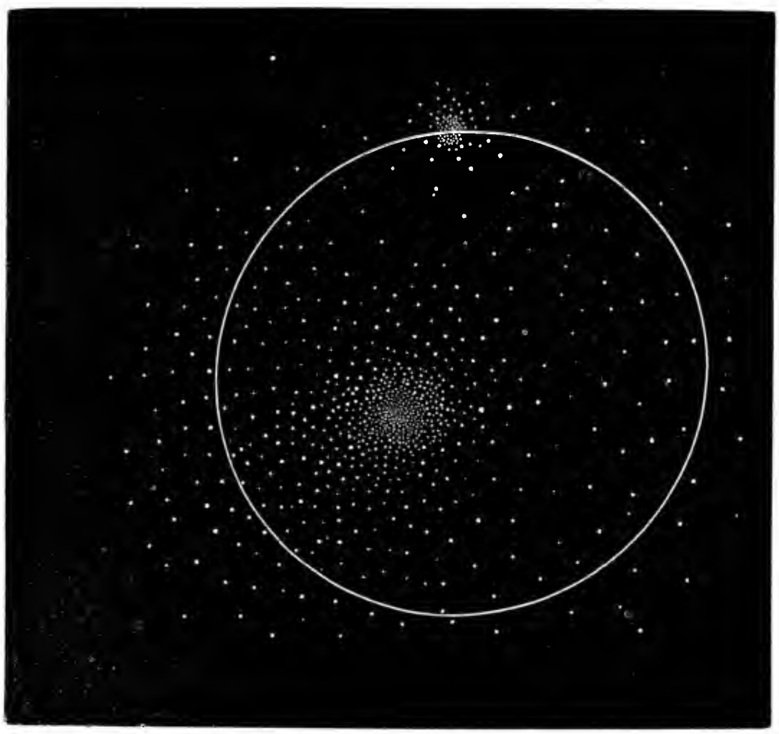

FIG. 13.—Explanation of the variability of the bodies of Group II. (3) Minimum variation. Under the conditions represented, the smaller swarm will never be entirely out of the larger one, and at periastron the number of collisions will not be very greatly increased; consequently the variation in the amount of light given out will be small.

recorded by Dunér. I find they may be grouped as follows:—

1. *All bands visible but narrow.*

No. in Dunér Cat.	Name.	Max.	Min.	Period.
269	μ Cephei ...	4?	5?	irreg.

2. *Bands well marked, but feebler in Red.*

No. in Dunér Cat.	Name.	Max.	Min.	Period.
186	W Herculis (? V)	>8	<12	290?
222	R Sagittarii	7	12	270
81	S Hydræ ...	7·8	<12	256

3. *Bands wide and strong, especially 7 and 8.*

No. in Dunér Cat.	Name.	Max.	Min.	Period.
23	T Arietis ...	8	9–10	324
37	R Tauri......	7·8	<13	326
68	S Canis Min.	7	<11	332
76	R Cancri ...	6	<11–12	360
91	R Leonis Min.	5	10	313
100	R Urs. Maj.	6	12	303
106	R Crateris...	>8	<9	160?
118	R Corvi......	7	<11–13	319
159	R Boötis ...	6	12	223
165	S Libræ......	8	12–13	190?
170	R Serpentis.	5·6	<11	358
181	U Herculis..	6·7	11–12	408
192	S Herculis...	6	12	303
195	R Ophiuchi.	7·8	12	302

4. *All bands markedly wide and strong.*

No. in Dunér Cat.	Name.	Max.	Min.	Period.	
18	*o* Ceti	2–5	8–9	(331)	
20	R Ceti ...	8	<13?	167	
29	*ρ* Persei ...	3·4	4·2	irreg.	Many lines.
92	R Leonis ...	5	10	313	
141	R Hydræ ...	4·5	4·0?	(437)	
158	V Boötis ...	—	—	—	
166	S Coronæ ...	6	12	361	
184	*g* Herculis ...	5	6	irreg.	Nearly circular orbit.
196	*α* Herculis ...	3	4	irreg.	
217	R Lyræ ...	4·3	4·6	46	
221	R Aquilæ ...	6·7	11	345	
239	*χ* Cygni ...	4	13	406	
293	R Aquarii ...	6	11	388	

5. *Bands wide, but pale.*

No. in Dunér Cat.	Name.	Max.	Min.	Period.	
3	T Cassiopeiæ	6·7	11	436	
125	T Urs. Maj.	7	12	256

210	T Herculis	7	12	165	
4	R Androm.	5·6	<12–13	405	

6. *Bands thin and pale.*

No. in Dunér Cat.	Name.	Max.	Min.	Period.	
50	*α* Orionis ...	1	1 4	irreg.	
128	S Urs. Maj.	7·8	11	225	
187	R Draconis	6·7	11–12	247	
238	S Vulpec. ...				
261	R Vulpec....	7·8	13	137	

A glance at the above tables will show that the kind of variability presented by these objects is a very special one, and is remarkable for its great range. The light may be stated in the most general terms to vary about six magnitudes, from the sixth to the twelfth. This I think is a fair average; the small number of cases with a smaller variation I shall refer to afterwards. A variation of six magnitudes means roughly that the variable at its maximum is somewhere about 250 times brighter than at its minimum.[1]

I have already indicated that, with regard to the various origins of the variability of stars which have been suggested, those which have been always most in vogue consider the maximum luminosity of the star as the normal one; and indeed with regard to the Algol type of stars of short periods, which obviously are not here in question, there can be no reasonable doubt, that the eclipse explanation is a valid one; but in cases such as we are now considering, when we may say that the ordinary period is a year, this, explanation is as much out of place on account of period, as are such suggested causes as stellar rotation and varying amount of spotted area on a stellar surface, on account of range.

[1] Obtained by the formula $L_m = (2\cdot512)^n \cdot L_{m+n}$. For differences of 5, 6, 7 and 8 mag. we get

$$L_m = 100\cdot02 \cdot L_{m+5}$$
$$= 251\cdot24 \cdot L_{m+6}$$
$$= 631\cdot11 \cdot L_{m+7}$$
$$= 1585\cdot35 \cdot L_{m+8}$$

L_m = light of a star of magnitude m.
L_{m+n} = ,, ,, n magnitudes fainter

We are driven, then, to consider a condition of things in which the minimum represents the constant condition, and the maximum a condition imposed by some cause which produces an excess of light; so far as I know the only explanation on such a basis as this that has been previously offered is the one we owe to Newton, who suggested such stellar variability as that we are now considering was due to conflagrations brought about at the maximum by the appulse of comets.

How the Difficulty of Regular Variability on Newton's View is got over in mine.

It will have been noticed that the suggestion put forward by myself is obviously very near akin to the one put forward by Newton, and no doubt his would have been more thoroughly considered than it has been hitherto, if for a moment the true nature of the special class of bodies we are now considering had been *en évidence*. We know that at their minimum they put on a special appearance of their own in that haziness to which I have before referred as having been observed by Mr. Hind. My researches show that they are probably nebulous, if indeed they are not all of them planetary nebulæ in a further stage of condensation, and such a disturbance as the one I have suggested would be certain to be competent to increase the luminous radiations of such a congeries to the extent indicated.

Some writers have objected to Newton's hypothesis on the ground that such a conflagration as he pictured could not occur periodically, but this objection I imagine chiefly depended upon the idea that the conflagration brought about by one impact of this kind would be quite sufficient to destroy one or both bodies, and thus put an end to any possibilities of rhythmically recurrent action. It was understood that the body conflagrated was solid like our earth. However valid this objection might be as urged against Newton's view, it cannot apply to mine, because in such a swarm as I have suggested, an increase of light to the extent required might easily be produced by the incandescence of a few hundred tons of meteorites.

I have already referred to the fact that the initial species of the stars we are now considering have spectra almost cometary, and this leads us to the view that we may have among them in some cases swarms with double nuclei—incipient double stars, a smaller swarm revolving round the larger condensation, or rather round their common centre of gravity. In such a condition of things as this, it is obvious that, as before stated, in the swarms having a mean condensation this action is the more likely to take place, for the reason that the more the outliers of the major swarm are drawn in, the more likely is the orbit of the smaller one to pass clear. The tables show that this view is entirely consistent with the facts observed, for the greater number of instances of variability occur in the case of those stars in which, on other grounds, mean spacing seems probable.

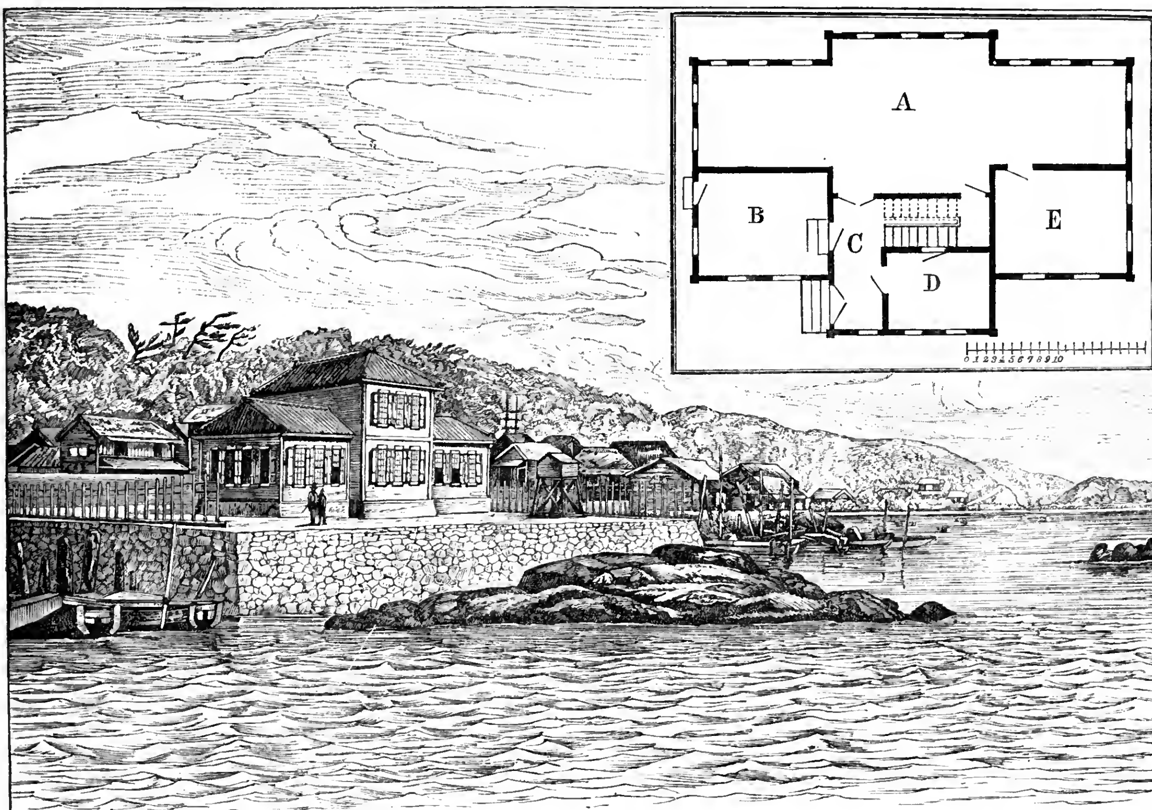
The Cases of Small Range.

So far, to account for the greatest difference in luminosity at periastron passage, we have supposed the minor swarm to be only involved in the larger one during a part of its revolution, but we can easily conceive a condition of things in which its orbit is so nearly circular that it is almost entirely involved in the larger swarm. Under these conditions, collisions would occur in every part of the orbit, and they would only be more numerous at the periastron in the more condensed central part of the swarm, and it is to this that I ascribe the origin of the phenomena in those objects—a very small number—in which the variation of light is very far below the normal range, one or two magnitudes instead of six or seven. Of course, if we imagine two subsidiary swarms, the kind of variability displayed by such objects as *β* Lyræ is easily explained.

NATURAL SCIENCE IN JAPAN.

WITH the close of our eventful Jubilee year there was completed the first volume of a new journal of science which is destined to play a very important part in the advance of knowledge. We refer to the Journal of the College of Science of the Imperial University of Japan, already noted in these pages.

This periodical is issued under the joint editorship of four professors in the College whence it originated. These gentlemen, one only of whom is an Englishman, constitute a publishing committee: they have adopted the wise plan of issuing all communications on all subjects recognized within the one cover, and under their supervision there have already appeared a series of original papers of considerable interest, so far at least as those biological are concerned. The work is being well done: authors, editors, publishers, and craftsmen appear to be working harmoniously in the production of a journal which, while it reflects the utmost credit on all, leaves nothing to be desired. Twenty-one original monographs have been set up, three of them in German, the rest in English. Of these five are biological, while six are devoted to physics, four to chemistry, three to seismology, and two to geology proper. It is to the first-named that we wish now to refer. The first paper published deals with the life-history of a parasite (*Ugimya sericaria*) which works fearful havoc among the silkworms in Japan: this monograph is in itself interesting, apart from its intrinsic merit, as showing that our Eastern friends are fully alive to the so-called practical application of their work. This and other valuable papers which we might name testify most satisfactorily to the thoroughness of, at any rate, one side of the undertaking; others there are which show that



The Marine Biological Station of the Imperial University at Misaki.

these investigators are fully prepared to face some of the most formidable problems now exercising the mind of the zoologist, and in dealing with such problems they display a diligent attention and cautious generalization, such as are occasionally looked for in vain in writings nearer home. If this excellent beginning is, in these respects, indicative of that which is to follow, only results of the greatest value can ensue.

Of the zoological communications two are exceptional—we refer to those contributed by Prof. K. Mitsukuri, of the Imperial University, Tokio. One of these, on the germinal layers in Chelonia (produced in conjunction with his assistant, Ishikawa), has previously appeared in our own *Journal of Microscopical Science*. The other is deserving of especial comment, for it brings tidings of the establishment of a marine biological station of the Imperial University, at Misaki.

Misaki is a fishing settlement to the west of the Bay of Tokio, easily accessible, we are told, from Tokio or Yokohama in a day. Its waters have a direct interest for Western zoologists, in the fact that they have given birth to most of those museum specimens of Hyalonema, with which the skilful Japanese so long duped the rest of the world. Geographically, the relations of Japan to Asia may be appropriately compared with those of Britain to Europe: in their greater climatic variations, however, the Easterns have an advantage, if only by way of variety in the fauna and flora thereby induced. Again, Misaki, says Prof. Mitsukuri, has "long been a favourite collecting ground for naturalists; almost every group of animals is represented in this region in more or less abundance," and he gives it as his opinion that zoologists have by no means "become acquainted with even a small part of all the interesting animals to be found." When we reflect upon this, mindful of the climatic features of the district, and in view of the enumeration given of known inhabitants of its waters, great expectations are conjured up, and the importance of the enterprise upon which our friends have embarked becomes self-evident.

The station has been founded by the Department of Education and the authorities of the Imperial University, as a special adjunct to the biological laboratories of the latter. As it is fair to assume that the governmental body will, like all others, expect "something practical" for its money, we anticipate that attention will early be given to questions of economic importance. The Japanese have a fishing population of more than 1,500,000 active workers, while it is computed that 36,000,000 persons, in all, are more or less dependent upon fish as food. When, in view of the total area and population of our own islands as compared with those of Japan, it is remembered that our own fishing population numbers little over 540,000, it becomes needless to point out that the Japanese are *par excellence* a fishing folk. They moreover appear to possess an ancient but limited literature on the subject.

The establishment, by the Japanese, of this and other similar institutions has been necessitated by the adoption of the products of Western civilization, almost, it would seem, in return for that "devout and learned admiration" so long accorded them by the Western nations. Rapid indeed has been their progress under influences which are bringing their wares into open competition with Western markets, and who shall say but that we proud Europeans may not yet be, perforce, to no small extent dependent upon them for edible produce?

The founding of this marine station is, biologically, a sign of the times. More than this, however. It is a mo ement upon which, in the long run, the intellectual as well as the commercial prosperity of a large section of the community must depend; for in the spread of that true science which seeks to unravel the knowledge of causes, there now lies the only sound basis for national prosperity. Prof. Mitsukuri's association with the undertaking is, in itself, a guarantee that these interests will be upheld. His earlier work was executed under the guidance of, and in fellowship with, American subjects whose names will be for ever memorable in the history of marine zoology: his association with them and with the illustrious Balfour, and his acknowledged indebtedness to Dohrn, are, in themselves, auguries of success. We note with much satisfaction that "arrangements will be made by which students in the biological course of the University will be required to pass at least one term in the station": workers will be thus assured, and we tender them our sincere congratulations and hearty good wishes for a prosperous development of their enterprise. It must not be forgotten that the Japanese waters have lately yielded us the interesting Chlamydoselache, and it would be a most interesting circumstance should the far-famed Hyalonema, to which Prof. Mitsukuri so frequently reverts in his article quoted, receive final consideration at the hands of his countrymen.

The following is a brief description of the station itself, extracted from the original article. "The building is of plain wood, and one story high, except in the middle part, which has a second floor. The main laboratory-room (A), which occupies the whole sea-front, is 48 feet long, 12 feet wide at the two ends, and 18 feet in the middle, and is able to accommodate about ten workers. A number of small aquaria for the use of investigators will be placed in this room. Of the rooms at the back of the main laboratory, one (B) has a cement floor and is for assorting and preserving specimens brought in from the sea. Another (E) is to be used as the library-room, and a third (C) as the store-room. The second floor over the central part of the building is able to give sleeping accommodation for a few persons. From a tank placed outside the building, fresh sea-water is carried into the main laboratory-room and the assorting-room, and is delivered out of many facets." G. B. H.

THE AURORA IN SPITZBERGEN.[1]

THE best observations hitherto made on the aurora borealis are those made at Bossekop, by Bravais, during the expedition of the French corvette *Le Recherche*, 1838–40. Bossekop is also situated in the maximum zone of the auroras, on the coast of Northern Norway. Considering that Spitzbergen lies a little *north* of the same zone, and nearly on the same meridian as Bossekop, it was resolved that the observations of auroras should be made with the greatest possible care at the Swedish International Polar Station at Spitzbergen in 1882–83. This work was confided to Mr. Carlheim-Gyllenskiöld, and the auroral observations are the most complete that have been made by any of the international expeditions during that year. The results are now printed, and form a large quarto volume of 409 pages, with a great number of tables, illustrations, and figures. The results confirm and enlarge those of Bravais, and of other observers of this brilliant phenomenon.

(1) The first question is the determination of the mean co-ordinates of the auroral arch. A mean of 371 measurements gave the azimuth of the culminating point or summit of the auroral arch in S. 24° 12′ E. As early as 1834, Argelander, in Åbo, Finland, found that the azimuth of the culminating point of the auroral arch differs about 10° from the magnetic meridian. At Bossekop the magnetic declination was N. 10° 8′ W., and the declination of the culminating point of the auroral arch N. 22° 4′ W., the anomaly being, of course, about 11° W. The magnetic declination at Cape Thordsen was found to be N. 12° 45′ W., and of course the auroral anomaly from the magnetic meridian was 11° 27′ W.

(2) Eighty-seven measures on the position of the corona borealis were made, and the position of the centre of the corona was found nearly in the magnetic zenith, and *not* in the same vertical as the highest point of the arch. The means are:—

Position of the centre of the corona	H = 79° 55′ ...	Az. = S. 7° 12′ E.
Position of the magnetic zenith	H = 80 35 ...	Az. = S. 12 4 E.
Position of the culminating point of the arch	H = — ...	Az. = S. 24 12 E.

This confirms the measurements made during the past century by Wilcke, Mairan, and others.

(3) The breadth of the auroral arches varies with their elevation above the horizon. The arches consist of rays running in the direction of the breadth of the arch, and converging towards the magnetic zenith. Thus they form a long fringe of rays parallel to the dipping-needle, suspended, like a curtain, from east to west, but with a small extent of breadth from north to south. If this curtain of rays moves from the horizon to the zenith, the breadth varies according to the laws of perspective. The formula gives the greatest breadth at a height of 45°. In the neighbourhood of the zenith the arches are very narrow, stretching as a luminous band across the heavens.

(4) Besides the arches and rays, the auroral light sometimes formed a true spherical zone parallel with the earth's surface, thus floating in space as a horizontal layer of light, often crossed by several arches. This form is seldom to be seen in lower latitudes. These auroral zones were apparently much broader in the zenith than at their extremities nearer to the horizon. When such an auroral zone was lying wholly over the heavens, with the excep-

[1] "Observations faites au Cap Thordsen, Spitzberg, par l'Expédition Suédoise." Tome II. (1) Aurores boréales. Par Carlheim-Gyllenskiöld.

tion of a low segment near the horizon, a dark segment was produced by contrast. Sometimes the luminous zone was broken, and then dark spots or irregular spaces were produced in the same way. These dark spaces were frequently seen tinted with a faint rosy light.

(5) The movement of the arches is ordinarily reported to be from north to south, at places situated to the south of the maximum zone, and, from the opposite direction, at places within the maximum zone. Thus, at different stations between the latitude of Rome and the latitude of Bossekop, 69·6 per cent. of the auroral arches have moved from the north; at Mossel Bay, Franz-Josef Land, and Discovery Bay, on the contrary, 62·5 per cent. have moved from the south. At Cape Thordsen it was of course expected that the most part of the auroral arches would move from the south. Yet this was not the case. On the contrary, 57·6 per cent. moved from the north. The movements were, of course, almost the same in both directions.

(6) The anomalous forms of arches were very frequent, and were made a matter of accurate investigation. Sometimes an auroral arch presents the form of a sinuous band, or resembles a brilliant curtain with deep folds. At other times the arches appeared as regular spirals. Seen from the outside of the earth, or from above, the spirals were almost all contorted in a direction contrary to the motion of the hands of a watch, and the undulations folded as an S. The motion was, in 80 per cent., from west to east. The folds of the auroral draperies had very different dimensions on different occasions. Sometimes a regular arch showed only a slight undulation; at other times, only a part of an immense auroral drapery was seen above the horizon, as a pseudo-arch.

(7) Often, waves of light are running along the arches, and then the rays or beams are apparently in vivid motion. This appearance of the aurora is known in England as "the merry dancers." In 103 cases the waves were running from west to east, and in 101 cases from east to west. The mean angular velocity per second was 38′·6. For a mean vertical height of the aurora of 100 kilometres above the earth's surface, or 222 kilometres from the observer's eye, this gives the immense velocity of about 2·5 kilometres per second. The light of the aurora was often suddenly changing as to the distribution and intensity of light, but the geometrical form of the whole phenomenon was only slowly varying. The rays were sometimes observed to have a slow proper motion from west to east, or *vice versâ*.

(8) As to the classification of the auroral forms, the author rejects that of Weyprecht. The different forms of the aurora in the classification of Weyprecht are, in fact, only different views or projections, as, for instance, the forms III. = beams or rays, and IV. = corona. The corona results, according to the rules of perspective, when a large number of separate beams parallel to each other and to the direction of the dipping-needle seem to converge to one point, viz. the magnetic zenith. A regular and fully-developed arch consists, as we have said before, of a long fringe of rays, and so on. The author considers only two different forms of auroral light, viz. zones, or horizontal layers of light; and arches, composed more or less of distinct rays parallel to the dipping-needle. The arches present themselves in four different conditions: (1) arch, or a regular band; (2) band, or drapery; (3) spiral; and (4) pseudo-arch.

(9) The light of the aurora is, according to the author, of two kinds: (1) the yellow light, entirely monochromatic, and showing in the spectroscope the well-known yellow line of Ångström; (2) the crimson or violet light, resolved in the spectroscope into several rays and bands, spread over all parts of the spectrum. In the following table we give (I.) the lines observed by the author, (II.) the lines observed by several authors before the year 1884, and (III.) the spectrum of lightning, according to the observations of Herschel, Vogel, Schuster, and the author. The unity for wave-length is, as usual, the 0·0000001 of the millimetre.

I.	II.	III.
6306 ± 7·3	6294 ± 6·4	6300
5776 ± 3·0	5776 ± 3·0	—
5664 ± 3·0	5664 ± 3·0	5685
5568 ± 1·6	5570 ± 0·9	—
5353 ± 3·0	5353 ± 3·3	5338
5264 ± 2·5	5280 ± 1·8	5260
5228 ± 2·7	5226 ± 3·2	—
5001 ± 4·2	5003 ± 2·7	5004
4837 ± 10·7	4862 ± 1·5	4860
4707 ± 5·1	4702 ± 2·9	—
4642 ± 3·3	4636 ± 2·4	4632
4236 ± 6·7	4286 ± 4·4	—

There were twelve other extremely faint auroral rays to be seen occasionally, but their position could not be exactly observed.

As to the further discussion of the different auroral spectra and their supposed connection with different auroral forms, we must refer to the original paper.

(10) No sound was ever heard from the auroral light. The feeble rustling noise sometimes heard was observed to come from the loose agile surface-layer of snow driven to and fro by the lightest wind over the underlying layers. Nor was a "smell of sulphur" observed.

(11) As to the height of the aurora, it may first be mentioned that the aurora was never seen to descend below the mountains or the lower clouds. Only two or three times it is possible that the light was seen below the upper clouds. Yet sometimes the auroral light was seen to be reflected from the surface of the snow. Direct measures of the parallax from the end of a short base (573 metres), by means of auroral theodolites of Mohn's construction, gave an average height of 55·1 kilometres; from observations of the corresponding amplitudes and heights of the arches, according to Bravais' method, 57·7 kilometres; and by several other observations and calculations, about 60 kilometres was found to be the probable mean height of the aurora.

(12) As to the annual and diurnal periods of the aurora, no annual variation in the frequency could be proved. The apparent daily period gave a maximum at 8h. 50m. Göttingen time, or 9h. 13m. local time, in the evening; and a minimum at exactly the same hour in the morning. This apparent period must be corrected for the influence of the quantity of clouds and for the influence of the twilight. If F represents the apparent frequency of the aurora, and Q the quantity of clouds in tenth parts of the whole sky, there was found $F = 1 - 0·0730\,Q$, in taking for unity the apparent frequency when the heavens were totally clear.

Further, the apparent frequency when the sun was 10° 47′ below the horizon was the half of the true frequency, and the influence of the sun's light was sensible as far as to a depth of the sun of 17° 45′ below the horizon. Once only the aurora was seen when the sun was not more than 5° 25′ below the horizon.

Taking into account these sources of error, the true daily range has a maximum at 3h. 3m. p.m., and a minimum at 8h. 3m. a.m. local time.

Finally, there was also a well-marked daily range in the form of the aurora. The most brilliant phase of the phenomenon occurred at 4h. p.m.; the aurora then appeared as a complete regular arch. On the other hand, the minimum brilliancy took place at 9h. a.m.; the arches then were resolved into whirling fragments.

Upsala, April. H. HILDEBRANDSSON.

NOTES.

THE general arrangements for the Bath meeting of the British Association have now been made. The first meeting will be held on Wednesday, September 5, at 8 p.m. precisely, when

Sir H. E. Roscoe will resign the chair, and Sir F. J. Bramwell, President-elect, will assume the Presidency, and deliver an address. On Thursday evening, September 6, at 8 p.m., there will be a *soirée;* on Friday evening, September 7, at 8.30 p.m., a discourse on "The Electrical Transmission of Power," by Prof. W. E. Ayrton; on Monday evening, September 10, at 8.30 p.m., a discourse on "The Foundation Stones of the Earth's Crust," by Prof. T. G. Bonney; on Tuesday evening, September 11, at 8 p.m., a *soirée*. On Wednesday evening, September 12, the concluding general meeting will be held at 2.30 p.m. Excursions to places of interest in the neighbourhood of Bath will be made on the afternoon of Saturday, September 8, and on Thursday, September 13.

THE fourth session of the International Geological Congress will be opened on Monday evening, September 17, and will last during the whole of the week. The meetings will be held in the rooms of the University of London, Burlington Gardens. The Honorary President of the Congress will be Prof. Huxley; the President, Prof. Prestwich; the Vice-Presidents, the Director-General of the Geological Survey, the President of the Geological Society, and Prof. McK. Hughes; Treasurer, Mr. F. W. Rudler; and General Secretaries, Mr. J. W. Hulke and Mr. W. Topley. Up to the present date 395 geologists have signified their intention of being present. Of these 210 are British, and 185 foreign. The number of countries represented is 22.

THE Linnean Society holds its centenary celebration to-day. The following is the programme of the proceedings:—At 2.30 p.m. the President will receive the visitors. At 3 p.m. the President will take the chair. After introductory remarks by the President, and the formal business of the anniversary meeting, the Treasurer will lay before the meeting an account of the financial condition of the Society during the last century; the Secretaries will lay before the meeting a history of the Linnean books, herbarium, and other collections; the President will deliver the annual address. The following Eulogia will be pronounced: On Linnæus, by Prof. Thöre Fries, the present occupant of the Chair of Botany at Upsala; on Robert Brown, by Sir Joseph Hooker; on Charles Darwin, by Prof. Flower; on George Bentham, by Mr. W. T. Thiselton Dyer. The Linnean Gold Medal, instituted by the Society on the occasion of its centenary, will be presented to Sir Joseph Hooker (botanist), and Sir Richard Owen (zoologist). (In subsequent years the presentation will be alternately to a botanist and zoologist.) At 6.30 p.m. the annual dinner will be held at the Hotel Victoria, Northumberland Avenue, the President in the chair. To-morrow (May 25th), at 8.30 p.m., the President and Officers will hold a reception of the members and visitors in the Rooms of the Society, when the Linnean collections and relics will be exhibited.

THE late Mr. Cooper Foster, of Grosvenor Street, for many years senior surgeon to Guy's Hospital, was famous among horticulturists as a collector and grower of Hymenophyllums, Trichomanes, and Todias, popularly known as Filmy Ferns. With very few exceptions, the whole of these plants are extremely difficult to cultivate. The conditions under which they grow naturally are not easily imitated. Mr. Foster, however, contrived to keep a very rich collection of species, many of them unknown in gardens except at Kew, where the collection of Filmy Ferns is perhaps unique; and even Kew did not possess several kinds which Mr. Foster possessed. When it is remembered that these extremely delicate plants were cultivated in one or two small greenhouses at the back of a house in Grosvenor Street, Mr. Foster's success appears still more remarkable. After his death the Filmy Ferns were removed to his son's residence at Binfield, Berks. Recently, however, Mrs. Foster offered the whole collection to Kew, and it has lately been transferred to these Gardens, special accommodation having been provided for it in the house (No. 3) where the bulk of the Kew collection is grown. Among the most noteworthy of the plants comprised in the Cooper Foster collection are *Trichomanes reniforme*, a magnificent specimen a yard across, bearing hundreds of fine healthy leaves; *T. parvulum*, which has a compact cushion-like mass of tiny palmate leaves; *T. alabamense*, *Hymenophyllum æruginosum*, *H. chiloense*, *H. cruentum*, *H. flexuosum*, *H. Fosterianum*, *H. pectinatum*, *H. pulcherrimum*, and some grand masses of *H. demissum*. This magnificent gift to the national gardens at Kew will no doubt receive the appreciation from the public which its intrinsic beauty, scientific interest, and actual pecuniary value deserve.

MRS. EMMA W. HAYDEN has given to the Academy of Natural Sciences of Philadelphia in trust the sum of $2500.00, to be known as the Hayden Memorial Geological Fund, in commemoration of her husband, the late Prof. Ferdinand V. Hayden. According to the terms of the trust, a bronze medal and the balance of the interest arising from the fund are to be awarded annually for the best publication, exploration, discovery, or research in the sciences of geology and palæontology, or in such particular branches thereof as may be designated. The award and all matters connected therewith are to be determined by a Committee, to be selected in an appropriate manner by the Academy. The recognition is not to be confined to American naturalists.

ACCORDING to the *Colonies and India*, the appointment of Superintendent of the Botanical Gardens, Singapore, has become vacant owing to the death of Mr. Cautley in Tasmania.

M. HERVÉ MANGON, Member of the Paris Academy of Sciences, and President of the French Meteorological Councils died on the 16th inst., at the age of sixty-seven. He was Minister of Agriculture in the Brisson Cabinet, and was a high authority on drainage and agricultural improvements.

THE Pilot Chart of the North Atlantic Ocean for May show, that, generally, fine weather prevailed over that ocean during April. Storms accompanied by electric phenomena occurred about once a week north of the 40th parallel. A cyclonic storm of great strength was generated on April 15 in about 35° N. and 60° W., moving across the Banks from the 16th to the 18th, in which the wind reached force 11. There was also a gale of considerable strength to the north-eastward of the Azores during the second week of April, and a "norther" was felt in the western part of the Gulf of Mexico on the 13th. Considerable fog was met with off the Grand Banks, and southwards. The amount of ice encountered was unusually small, and was confined for the most part to the south-east coast of Newfoundland. Although it has been delayed in its southward movement by the unusual prevalence of south-easterly winds, it is now liable to appear in quantity, and to constitute a source of danger for several months. Careful observations of the Gulf Stream and the equatorial current are now being made at certain points by the United States steamer *Blake*.

A SODIUM salt of zincic acid has at last been obtained in the crystalline state by Messrs. Comey and Loring Jackson, of Harvard University (*Berichte*, 1888, 1589). Every analyst is aware that zinc hydrate is soluble in potash or soda, and although it has been presumed that zincates of the alkalies or compounds of the alkaline oxides with zinc oxide are formed under these circumstances by replacement of the hydrogen of the hydrate by potassium or sodium, no such compounds have hitherto been isolated. Messrs. Comey and Jackson, however, find that when a concentrated solution of zinc or zinc oxide in soda is shaken with alcohol the mixture separates on standing into two layers a heavier aqueous and a lighter alcoholic layer. When the treatment of the heavier layer with alcohol is repeated once or twice, it eventually solidifies to a mass of white crystals which melt below 100° C. Moreover, on allowing the alcoholic washings to stand, long brilliant white needles, often more than a centimetre in length, are deposited. These latter crystals differ very markedly in melting-point from those obtained from the aqueous portion, as they remain unfused even at 300°. They were finally purified and subjected to analysis, the results of which point very clearly to the composition $2NaHZnO_2 + 7H_2O$, or $2Zn(OH)(ONa) + 7H_2O$. Hence this new salt may be regarded as hydrogen sodium zincate. It is soluble in water and alcohol holding soda in solution, but is decomposed both by pure water and alcohol. The crystals obtained from the aqueous solution above mentioned appear to differ from those just described only in containing more water of crystallization, the amount of which has not yet been fixed with certainty. The fact that zinc oxide behaves so negatively towards the more positive alkalies, playing as it evidently does the *rôle* of an acid, is now happily a proved one, and it is to be hoped that the American chemists will continue their researches until they have been as fortunate in preparing the normal salt of zincic acid.

AT the last meeting of the Asiatic Society of Japan, the Rev. J. Batchelor read a paper on "Some Specimens of Aino Folk-Lore." There were seven of these taken down as they were sung, chanted, or recited by the Aino bard or story-teller. After telling these stories, Mr. Batchelor observed that among the Ainos there are still prophets and prophetesses, but they limit their powers now to telling the cause of illness, prescribing medicine, using charms, and the like. A person when prophesying is supposed to sleep or otherwise lose consciousness, and to become, so to speak, the mouthpiece of the gods. The prophet is not even supposed to know what he himself utters, and often listeners cannot understand the meaning of the utterances. The burden of the prophecy sometimes comes out in jerks, but more often in a kind of sing-song monotone. Mr. Batchelor described one scene of Aino prophesying at which he was present. "Absolute silence reigned around, old men with gray beards sat with eyes full of tears, in rapt attention; the prophet himself was apparently quite carried away with his subject; he trembled, perspired profusely, and beat himself with his hands. At length he finished exhausted, and as he opened his eyes for a moment, they shone with a wild light." During the discussion which followed, it was stated that the author of the paper was engaged in the preparation of an Aino dictionary, for which seven or eight thousand words had already been collected. "Such a dictionary," said Prof. Chamberlain, "would in all likelihood be a kind of tomb in which the rapidly dying language would remain enshrined for ages. Even now it was striking to observe how all except the oldest men and women were really bi-lingual, speaking Japanese as easily as Aino."

MR. BRUCE FOOTE, Superintendent of the Geological Survey of India, lately contributed to the Asiatic Society of Bengal some most interesting "notes" on recent Neolithic and Palæolithic finds in Southern India. These notes have now been reprinted from the Society's Journal. One of the facts to which he calls attention is that "the old Stone-folk" of the Bellary-Anantapur country, where great numbers of Neolithic settlements have been found, selected granite-gneiss hills as the sites of their settlements. Four considerations may, he thinks, have influenced them in this choice:—(1) The more perfect isolation of the granite-gneiss hills, which mostly rise singly out of the plains, or, if in clusters, are yet individually detached, and therefore more suitable for defence than posts on continuous ridges, such as are generally formed by the schistose rocks. Some of the granite-gneiss hills are nearly perfectly castellated by the disposition of the rock-masses. (2) Rock-shelters of great efficiency and comfortable terraces are to be found in numbers on many of the granitoid hills, but hardly ever on the schistose hills. (3) The collection of rain water and its storage would, from the nature of the ground, be much easier on the average granitoid rock than on the average schistose hill. (4) The schistose hills are, in very many cases, generally, in fact, surrounded by a heavy and broad talus most detrimental to easy agricultural work. The granitoid hills, on the contrary, form, as a rule, no great talus, but rise up straight out of the great cotton-soil plains, so that the Neolithic field labourers could have been quite close to places of refuge in cases of attack from other tribes, and yet have been able to carry on their agricultural work.

AT the last meeting of the Archæological Society of Sweden, Herr N. F. Sander read a paper on the wholly or partly undeciphered runic inscriptions in Sweden, which he divided into three classes: (1) those composed of ordinary runic letters, but in which the runic "staf" or sign I, when signifying *i* or *e* had purposely been left out, in one inscription even twenty-five times; (2) the conventional runic signs, which were really runic cipher; and (3) the so-called Sudermania "qvist" (sprig or faggot) runes, as well as the "ice" runes. Here the secret lay in the circumstance that the three "sets" of letters had been purposely misplaced, so that in the inscriptions the third set (*h, b, l, m, r*) came first; first set (*f, u, t, h, o, r, k*) second; and second set (*u, i, a, s*) third. Referring to seven of the first-named order of inscriptions which had recently been deciphered, Herr Sander stated that five of them, all situated in the province of Upland, had the same contents, and contained some curious objurgations. In four of them appeared the word *Pim* or *Piment* (*i.e.* a strong drink composed of wine, honey, and spice), which, as well as *Klaret*, was mentioned in the *Saga* of Rollo the Ganger and the Normans. All these inscriptions were referred to the close of the pagan age. One of them read as follows: "Reksessr, only Thynne's son (son of), assigned (to himself)—*i.e.* wedded—asa-Askra; (she) is daughter of Thynne-Signil and the giant." At the mouth of the River Åby, close to which this stone was found, is a little island called Thynne or Tönnö.

IN an interesting article in a recent number of the *Naturwissenschaftliche Wochenschrift*, Prof. Nehring discusses the question as to the origin of the dog. He expresses his belief that it is descended from various still-surviving species of wolves and jackals. The taming of jackals, he says, presents no particular difficulty, and many attempts to domesticate wolves have been successfully made in recent times. Herr Rongé has so completely tamed a young wolf that it follows him exactly as a dog might do.

THE United States Consul at Auckland, in a recent report, says that rabbits have so eaten out the ranges in New Zealand, that the capacity for maintaining sheep has greatly lessened, and the flocks have fallen off in numbers. At the Stock Conference of 1886 it was stated that rabbits reduced by a third the feeding capacity of land, and that the weight of fleeces had decreased by 1 lb. to 1½ lb. each. The number of lambs decreased from 30 to 40 per cent., while the death rate increased from 3 to 13 per cent. Since 1882, when the Rabbit Act became law, Government has expended £7000 on Crown lands alone, and it is estimated that during the last eight years private persons have spent £2,400,000 in extirpating rabbits. The methods generally in favour are fencing, poisoned grain (generally phosphorized oats), and ferrets, weasels, and stoats.

THE Canadian Minister of Agriculture in his report for the past year refers to various measures taken by the Government for the advance of scientific agriculture in the Dominion. Five experimental farms in various parts of the country were provided by the Legislature, a botanist and entomologist were appointed, and a large number of experiments to ascertain the roots and cereals most suited for the circumstances of Canada—especially its short summer—were carried out under scientific supervision.

A RICH gold-field has been discovered between the two rivers, Lava and Papanahoni, in Surinam. It is an open question whether this district of 20,000–25,000 square kilometres belongs to France or Holland. M. Condreau, the French traveller, who has been closely investigating the district, considers that it will be as productive as the gold-fields of Australia and California.

THE University of Christiania has despatched a zoologist, Herr J. Jversen, to Sumatra, for the purpose of collecting natural history objects for that institution.

A SUM of £550 has been granted by the Danish Government towards the expenses of publishing the zoological and botanical results of Lieut. Hovgaard's Arctic expedition in the *Dijmphna* in 1880–81. The work will soon be issued.

IN addition to a sum already granted, the Norwegian Government has given £300 towards the publication of Prof. Friis's ethnographical chart of the provinces of Tromsö and Finmarken.

THE number of visitors to the Natural History Museum, recorded by aid of Benton's "O" register up to 6 o'clock on Whit Monday, was 4567, and the Museum was open for two hours longer. This number compares with 6010 and 6589 admissions on the Whit Mondays of the two preceling years. During the week ending Saturday last, 149,583 persons visited the Museum in the present year, being an increase of 8000 on last year.

THE honorary degree of LL.D. has been conferred by the McGill University, Montreal, upon Prof. W. Fream, B.Sc. Lond., of the College of Agriculture, Downton, Salisbury, in recognition of his contributions to agricultural science and of his services to Canadian agriculture.

MUCH interest has been excited by the successful transplantation of nerve from a rabbit to man. The operation was performed by Dr. Gersung, of Vienna, and the patient was Dr. von Fleischl, Professor of Physiology in the University of that city. Sixteen years ago Dr. von Fleischl accidentally wounded himself while conducting a *post-mortem* examination, and the consequent severe inflammatinn of his right arm and hand led ultimately to the loss of the terminal joint of his thumb. The end of the stump having become painful, amputation somewhat further back was performed. This was followed by the formation of "neuromata." In the hope of obtaining relief he underwent several fruitless operations. Ultimately, Dr. Gersung suggested that the nerves might be repaired, and the missing portions replaced, by means of fresh nerve taken from a rabbit. The *Times* of Tuesday gives the following account of the operation:—"Just as there is nothing special in any individual human nerve, and as any one of them would be capable of discharging the duty of any other, so, it may be assumed, there is no difference between the endowments of the nerves of man and those of the lower animals, which fulfil identical functions in an identical manner. It was, therefore, inherently probable that the nerve of an animal, if a piece could be obtained of the proper size and length, and if transplantation and union could be successfully effected, would suffice to make good any loss of nerve in man; and, in the present instance, which is, we believe, the first of the kind on record, not only have the transplantation and union been successful, but the new piece of nerve seems to have overcome the tendency of the old to undergo degeneration of structure at its divided extremity. A portion, six centimetres in length, of the great nerve of a rabbit's thigh was selected, and was so removed from the freshly killed animal as to include the natural bifurcation of the main trunk into two branches. The divided stem was secured by stitches to the stump of the nerve in Prof. von Fleischl's arm, and the ends of the branches were secured in like manner to the nerve terminations which remained in his fingers, and which were rendered useless by their separation from the trunk to which they belonged. The whole operation, as a matter of course, was conducted with strict adherence to those principles of antiseptic surgery without which failure would have been more than likely; but, by the observance of which, union, almost anywhere or of any thing, can with a near approach to certainty be secured. The wound healed kindly, the transplanted nerve soon became at home in its new position; and already, after the lapse of a little more than two months, it is reported that sensation is returning to the fingers. At the same time there has been no return of pain, and no fresh indication of the development of neuromata, so that hope of an absolutely successful issue may now with some confidence be entertained."

THE additions to the Zoological Society's Gardens during the past week include three Cape Crowned Cranes (*Balearica chrysopelargus*) from Zanzibar, presented by Colonel E. Smith; two Peregrine Falcons (*Falco peregrinus*) from India, presented by Mr. J. Davidson; a Gannet (*Sula bassana*), British, presented by the Baroness de Taintegnies; a Three-toed Chalcis (*Chalcides tridactylus*) from France, presented by Mr. J. C. Warburg; an Indian Python (*Python molurus*) from India, received in exchange; an Elliot's Pheasant (*Phasianus ellioti* ♀) from China, purchased; an American Bison (*Bison americanus*), a Great Kangaroo (*Macropus giganteus* ♂), seven Suricates (*Suricata tetradactyla*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET 1888 *a* (SAWERTHAL).—Several computers having shown that the Cape observation of this object made on February 18 cannot be harmonized with those made since perihelion by means of parabolic elements, Prof. Lewis Boss has computed elliptic elements for it, based on the above-mentioned Cape observation, and observations obtained at Albany on March 17 and April 18. His first effort was to find a parabolic orbit from the last two observations, and another, also made at Albany, on March 30; but the resulting parabola not only entirely failed to satisfy the Cape observation, but also left residuals too large to be admitted, for other observations at his disposal which had been made since perihelion. The ellipse, on the contrary, which he obtained from the places of February 18, March 17, and April 18 satisfied these other observations very fairly, the largest differences being given by the observation of March 30, viz. (C – O)—

$$\Delta\alpha = -8''\cdot5. \qquad \Delta\delta = -7''\cdot2.$$

The residuals point to a somewhat larger eccentricity than that given below, but are probably due in great part to comparatively small errors in the first and last observations used.

The elements are as follow:—

$$T = 1888 \text{ March } 16\cdot9987 \text{ G.M.T.}$$

$$\left.\begin{aligned} \omega &= 359^\circ\ 54'\ 58''\cdot4 \\ \Omega &= 245\ \ 22\ \ 46\cdot6 \\ i &= 42\ \ 15\ \ 23\cdot1 \end{aligned}\right\} 1888\cdot0$$

$$\log e = 9\cdot997790$$
$$\log q = 9\cdot844329$$
$$\text{Period} = 1615 \text{ years.}$$

Prof. Boss suspects, however, that the true period will be found decidedly greater than 2000 years.

$$x = r\,[9\cdot898389]\sin(v + 328^\circ\ 9'\ 7''\cdot6).$$
$$y = r\,[9\cdot999694]\sin(v + 236\ \ 29\ \ 13\cdot9).$$
$$z = r\,[9\cdot787085]\sin(v + 323\ \ 42\ \ 17\cdot9).$$

In the same number of *Gould's Astronomical Journal* in which the above elements appear, the Rev. G. M. Searle gives an independent elliptic orbit very closely resembling that computed by Prof. Boss. The first two places used are the same as those Prof. Boss employed; the third is one obtained on April 16 at Harvard College. Prof. Boss gives the following ephemeris for Greenwich midnight:—

GEOGRAPHICAL NOTES.

Referring to the ethnology of the Himalayan hill region o Sikkim, where a small British force is at present in occupation, the *Madras Mail* says that the population may, broadly speaking, be divided into three nationalities: the Lepchas, who are the aborigines; the Nepalese immigrants, now forming nearly half the entire population; and the Bhuteas, or Bhutanese, who very closely resemble the Tibetans, and are pure Tartars. It is remarkable that the last-named are like the Chinese in the make of their hats, clothes, and boots, and in their pig-tails, but their language is somewhat like Turkish in its sound. It is supposed that this people originally came from Tibet, though they apparently derive their name from Bhutan, which lies to the east of Sikkim. They are tall, strong, and hardy, though they are accused of being lazy. They have their Buddhist temples, and erect long poles round their houses, with paper streamers on which are printed prayers in Chinese-looking characters. One may often meet them on the roads twirling their praying-machines, which are cylinders of brass or copper, with a printed roll of prayer inside, and small weights attached to it to make it revolve when once it is set going. It is thought that amongst them, like the Tibetans, polyandry prevails. The women are large and coarse-featured; they wear thick woollen clothes of bright colours, and numerous massive gold and silver ornaments. Some of them smear themselves with a brownish ointment which makes their faces appear as if a coating of French polish had been put on. With regard to the aborigines of Sikkim, they are a Mongolian race, short and stout. In appearance they resemble closely the Nepalese, though, far different from the latter, who are brave soldiers, they are the most arrant cowards. They live by cultivating small tracts of the forests, which they clear by setting fire to the trees and brushwood, and move to a fresh spot each year. As may be supposed, their agriculture is of the most primitive description, and in their language they have no word for a plough. They worship the forces of Nature under the form of demons; the Bhuteas also, though professed Buddhists, propitiate evil demons, the same sort of imaginary beings as the Nats of the Burmese. The Lepchas are monogamous. The race is gradually dying out. The Limboos are a race of half-breeds between the Nepalese and the Lepchas, but resembling the former more than the latter. There are several similar mongrel races to be found in Sikkim, for the Nepalese immigrate in vast numbers, being driven out of their own country by press of over-population. Few ever return to their own country, and great numbers of them work as coolies on the tea estates. Their religion is a mixture of Buddhism and Brahminism, and they boast of their caste distinctions. Many of them carry curved weapons in their belts, while the Bhuteas and Lepchas use straight-bladed weapons. The Bhutea sword is like that of the old Roman legionary, but the hilt has no guard, after the Mongolian fashion. Amongst the jungles of Perai there are some curious aboriginal tribes, who do not appear to suffer from the malaria which attacks everybody else who sets foot in their territory; but it is said that if they leave their jungles they are immediately attacked themselves by fever, the malarial poison with which they have become inoculated thus finding an exit when they quit their own locality. All the natives of the plain call these races indiscriminately "Pahariyas," or "hill-men," who, though they differ from each other, differ still more from the inhabitants of the plain in their language and mode of life. They are all mountaineers and Mongolians, and have all great physical strength. A story is told of a Bhutea woman who once carried a grand piano up the Ghaut from Punkabari to Darjeeling in three days, and arrived on the third day quite fresh and unexhausted at her destination with her burden on her back.

A recent number of the *China Review* (vol. xvi. No. 3) contains a long paper by Mr. Taylor, whose publications on

Formosa and its people have frequently been noticed in these columns, entitled "A Ramble through Southern Formosa." It really describes a long journey along the almost wholly unknown east coast, and has much information respecting the various tribes, their relations to each other and to the Chinese Government—the Tipuns, Paiwans, Diaramocks, Amias, and others. Mr. Taylor refuses to discuss gravely the theory of a cataclysm put forward to account for the aborigines in Formosa. "One might just as well introduce the mythical convulsion which lost Atlanta to Europe, and detached Great Britain from the neighbouring continent, to account for the painted savages Cæsar found in England." The Tipuns are probably descended from emigrants from some northern islands, probably Japan; the Paiwans as a rule inhabit the mountains of the interior, and are head-hunters, a cruel, predatory, and passionate race, probably of Malay origin, and the very earliest settlers in Southern Formosa. The Pepohoans probably came from Loochoo; they have no language of their own, speaking only Chinese, while all the other tribes have their own tongue. The Diaramocks are the most dreaded tribe of the south part of the island; they are reputed cannibals, but Mr. Taylor doubts whether they are not accused without cause. The paper concludes with some vigorous engravings of representatives of the different tribes, including a Diaramock, a Tipun chief, an Amia, a Paiwan, a Tipun warrior, a Nicka, and Tipun weapons.

THE *Bollettino* of the Italian Geographical Society for April publishes the results of some preliminary studies, by Prof. Giulio Beloch, of the Roman University, on the vital statistics of Italy during the last three centuries. According to these studies, the total population of the peninsula has increased from a little over 11,000,000 in 1550 to 13,000,000 in 1700, 16,500,000 in 1775, over 18,000,000 in 1880, and nearly 30,000,000 in 1887. The growth of the population for some of the larger States is given as under:—

States.	Year.	Pop. in millions.	Year.	Pop. in millions.	Year.	Pop. in millions.
Naples ...	1511	2·7	1700	3·0	1770	4·09
Sicily	1570	1·07	1714	1·12	1770	1·48
States of the Church ...	1560	1·6	1701	1·98	1769	2·17
Tuscany ...	1562	0·8	1738	0·89	1766	0·94
Venetia ...	1548	1·6	1700	1·8	1766	2·24
Milanese ...	1542	1·0	1724	1·1	1773	1·1
Piedmont ...	1569	1·05	1723	1·55	1773	2·3
Sardinia ...	1575	0·15	1728	0·3	1775	0·42

A GEOLOGICAL Expedition, under the leadership of MM. Ivanoff and Konshin—the two well-known investigators of the geology of Turkistan—is to be sent out this summer for the exploration of the littoral region of Russian Mantchuria. The orography of this region is hardly yet known, and the Expedition will certainly throw some light on the structure of the chains of mountains which are still hypothetically represented on our maps.

THE IRON AND STEEL INSTITUTE.

THE annual meeting of the Iron and Steel Institute took place last week at the theatre of the Institution of Civil Engineers, under the presidency of Mr. Daniel Adamson. On the motion of the President, His Royal Highness the Prince of Wales was unanimously elected an honorary member. Sir Henry Bessemer presented the Bessemer medal to the President, and referred in the course of his remarks to the circumstance that whereas in Sheffield, the stronghold of steel-making, he could find no one to investigate his process when he first brought it out, fortunately for him—and he might add, fortunately for the world—their President, Mr. Daniel Adamson, did so, and having satisfied himself as to its applicability determined to employ it. The President, whose investigations with regard to steel are well known, thanked Sir Henry Bessemer and the Council of the Institution for the award, and referred to his early connection with Bessemer steel, which metal he had continued to use ever since.

The President then delivered the annual address, which was mainly statistical in character. The Iron and Steel Institute had been nineteen years in existence, during which period 2116 members had been elected, including seventy-two elected at the present meeting. He drew attention to the falling off which had taken place in the production of manufactured iron in this country since 1884, and the large increase in the production of steel during the same period. Thus in 1884 about one and a quarter million tons of Bessemer steel ingots were produced, and in 1887 about two million tons, being an increase of about 60 per cent.; in 1884 nearly half a million of tons of Siemens open-hearth steel ingots were cast, and nearly a million tons last year, the actual increase during the period being over 106 per cent., besides which plant is at present in course of erection estimated to produce another quarter of a million tons annually. During the same period there has been an enormous increase in the application of steel to shipbuilding purposes. Thus from a table supplied to the President by Mr. William Parker, Chief Engineer to Lloyd's Registry of British and Foreign Shipping, it is found that whereas in 1878, under 3000 tons of steel were employed in the manufacture of steamers and sailing-vessels built under Lloyd's survey, and over 300,000 tons of iron, last year over 210,000 tons of steel were employed and about 52,000 tons of iron. The proportional increase in the use of steel in the last three years has been about cent. per cent., and the falling off in the use of iron during the same period 350 per cent. Before leaving the subject of steel, the President referred to the papers read at the Institution of Civil Engineers on "Manganese in its Application to Metallurgy," and on "Some Novel Properties of Iron and Manganese," wherein it was shown that whereas 2·5 to 7·5 per cent. of manganese in steel makes it as brittle as glass, breaking under a much less transverse load than cast iron, 12 to 14 per cent. of manganese in the metal secures high carrying power with great elongation. Thus a bar of the composition—carbon 0·85 per cent., silicon 0·23 per cent., sulphur 0·08 per cent., phosphorus 0·09 per cent., and manganese 13·5 per cent., carried a load of 57·02 tons to the square inch, and took a permanent set at 29½ tons, with an elongation of 39·8 per cent. This metal is toughened by heating it to a high temperature, and plunging it into water at a temperature of 72° F. It is difficult to machine, which would militate against its practical application for many purposes, unless cooling in water whilst developing strength and toughness should also have a softening tendency. The President concluded his address by drawing attention to the influence of the alloys they contain on the various applications of pig metal, as outside of high-class hæmatites that are used for the manufacture of Bessemer and open-hearth steel, selections may be made giving the highest results without using some of the higher-priced irons that are now considered necessary for given purposes.

Mr. Carbutt, President of the Institution of Mechanical Engineers, in proposing a vote of thanks to the President for his address, drew attention to the interesting circumstance noted by Mr. Parker that 100 tons can now be carried one mile by steamships at the rate of thirteen miles an hour, at a total cost, including fuel, insurance, &c., of seven-eighths of a penny.

The papers read and discussed at this meeting ranged over a large variety of subjects. Mr. T. Turner's paper on "Silicon and Sulphur in Cast Iron," read at a previous meeting, was discussed. The conclusions at which the author arrives are that in the blast furnace three chief agencies are at work tending to eliminate sulphur, of which in Cleveland practice not more than one-twentieth passes into the iron: (1) a high temperature tends to prevent the absorption of sulphur by iron; (2) a slag rich in lime readily combines with sulphur; and (3) the amount of sulphur actually retained by the metal is influenced by the proportion of silicon and probably certain other elements present in the iron—the more silicon the less sulphur. This paper was discussed by Messrs. Snelin, Gautier, Riley, Bauerman, and Sir Lowthian Bell; but the author, in his reply on the discussion, considered that nothing had been brought forward to disprove what he maintained, viz. that if they put silicon and sulphur together in iron, they would not combine there, the sulphur would pass off and the silicon remain.

Mr. Gautier read a paper on the melting in cupola furnaces of wrought iron or steel scrap mixed with ferro-silicon, the conclusion at which he arrived being that ordinary wrought-iron scrap so heated may yield results as good as those obtained from castings made with ordinary steel scrap. This conclusion was contested, however, by various speakers in discussion.

A paper read at the last meeting of the Institute by Mr. A. Wilson, on "The Use of Water Gas for Metallurgical

Purposes," was discussed. The author had found water gas and producer gas practically equal both as regarded cost of production and heating values.

Mr. H. Eccles drew attention, in a paper on "An Imperfection in Mild Steel Plates considered chemically," to want of care in sampling steel before casting, whereby defects in the ingots were rolled out into the plates; and it appeared in the discussion, as well as in a paper by Major Cubillo, on "The Manufacture and Treatment of Ordnance at Trubia," that the ingot was much improved when the steel was made and heated in a radiation furnace. Another paper by Major Cubillo, on "Steel Castings for the Manufacture of Guns," gave rise to a highly technical discussion; as did also papers on "The Behaviour of Arsenic in Ore and Metal during Smelting and Purification Processes," by Messrs. Pattinson and Stead, and on "The Effect of Arsenic on Mild Steel," by Messrs. Harbord and Tucker.

The last paper read was on "A New Instrument for the Measurement of Colour, more especially as applied to the Estimation of Carbon in Steel," by Mr. H. Le Neve Foster. In the instrument are two fields of view under similar monocular conditions, freed from any errors which may arise from the introduction of unequal side lights, and also the different power of distinguishing colour that often exists in the eye of the observer; in conjunction with the instrument is a standard set of coloured glasses, each set being the same colour, but regularly graded for depth of tint. The instrument consists of a tube, divided by a central partition terminating at the eye-piece in a knife-edge, which, being inside the range of vision, is not seen when the instrument is in use. At the other end of the instrument are two apertures of equal size, and alterable in size or shape by means of diaphragms. The two apertures are divided by the thick end of the central partition, which, together with the sides, is recessed so as to hide the edges of the standard glasses, as well as the sides of the gauged glass vessels, which are used to contain the liquid that requires to be matched or compared. The only light coming to the eye must pass in equal quantity through the gauged glass vessel and the standard glasses respectively.

The instrument has been used by dyers, brewers, and sugar, and various other manufacturers. It forms a ready means of measuring the depth of colour in water, and is also applicable for Nessler's ammonia test as used in water analysis. For the estimation of carbon, the author finds the best results are obtained by dissolving 0·5 gramme of steel in 10 c.c. nitric acid, sp. 1·20, and boiling for twenty minutes, and then diluting to 50 c.c. and placing the liquid in a 1-inch cell. For mild steel this gives an easy colour to match, the results obtained agreeing well with those found by the Eggerty method.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for April, 1888 (vol. xxviii. part 4) contains:—A monograph on the species and distribution of the genus Peripatus, Guilding (plates 34 to 40), by Adam Sedgwick, F.R.S., gives an account of all the known species of the genus, with a bibliography of most of the literature relating to them. Many of the figures are coloured from nature.—Notes on the anatomy of *Peripatus capensis* and *P. novæ-zealandiæ*, by Lilian Sheldon, Bathurst Student, Newnham College, Cambridge. Gives details about the crural glands, the segmental organs, the accessory glands of the male, and the vas deferens.—On the construction and purpose of the so-called labyrinthine apparatus of the labyrinthine fishes (plate 41), by Dr. Nicholas Zograff.—Studies on the comparative anatomy of sponges; (1) on the genera Ridleia, n. gen., and Quasillina, Norman (plate 42), by Arthur Dendy.—Kleinenberg on the development of Lopadorhynchus, by G. C. Bourne. This paper gives a *résumé* of Prof. Kleinenberg's very detailed account of the development of the Polychæte Annelid Lopadorhynchus, which extends over 225 pages of the *Zeitschrift für Wissenschaftliche Zoologie.*

American Journal of Science, May.—The absolute wave-length of light, Part 2, by Louis Bell. In continuation of his previous communication the author here gives the angular measurements, and the details of the measurement and calibration of the gratings, together with the final results. He also inquires into the probable sources of error in some recent determinations of wave-length. His own final determination of the mean value of the absolute wave-length for the line D_1 is 5896·18 in air at 760 mm. pressure and 20° C. temperature, or *in vacuo* 5897·90, which he considers not likely to be in error by an amount as great as one part in two hundred thousand.—Three formations of the Middle Atlantic slope (continued), by W. J. McGee. In this paper the author deals with the Columbian formation alone, describing in detail the general characters of its fluvial and interfluvial phases. By the *fluvial* phase he understands the thicker and more conspicuous formations commonly occurring along the great rivers at and for some miles below the fall line, while the *interfluvial* comprises the thinner deposits forming the surface over the remainder of the coastal plain. These interfluvial deposits are shown to corroborate and extend the testimony of the deltas, all the phenomena conjointly recording a brief period of submergence of the entire coastal plain in the Middle Atlantic slope reaching 100 feet in the south and over 400 in the north, with coæval cold, long anterior to the terminal moraine period.—On some peculiarly-spotted rocks from Pigeon Point, Minnesota, by W. S. Bailey. The character and origin are discussed of some curious circular spots occurring here and there on the quartzites of Pigeon Point, a district projecting about 3½ miles into Lake Superior, and consisting mainly of a great dyke of coarse olivine gabbro or diabase.—The Taconic system of Emmons, and the use of the name Taconic in geological nomenclature (continued), by Chas. D. Walcott. In this paper the author deals with the subject of nomenclature, discussing the use of the names Taconic and Cambrian, and concluding with a classification of the North American Cambrian rocks.—Prof. R. D. Salisbury has some remarks on the terminal moraines of North Germany, and Carl Barus communicates a short note on the viscosity of gases at high temperature, and on the pyrometric use of the principle of viscosity.

Bulletin de l'Académie Royale de Belgique, March.—Remarks on some stone implements found in Spain by MM. H. and L. Siret, by A. F. Renard. Amongst the rich archæological finds recently made by MM. Siret in the Carthagena and Almeria districts are some polished stone hatchets of small size and beautiful workmanship. With a view to determining the material of which these implements were made, the author has subjected them to a careful analysis, and finds that this material is fibrolite, which occurs in many parts of Spain. In appearance it somewhat resembles jade, but its chemical composition and general properties show that it is quite distinct from that substance.—Determination of the variations in the specific heat of fluids near the critical point, by P. de Heen. It is suggested as a working hypothesis, that fluids are formed of molecular groups which may be called liquidogenic molecules. These groups and their constituent elements, presenting the aspect of little vortices, would appear simply to be the molecules as regarded in the gaseous state (gasogenic molecules). The transition from the liquid to the gaseous state at the critical temperature might then be thus interpreted. It may be admitted that at a given temperature the *gasogenic molecules* cease to move in closed curves, and describe the rectilinear trajectories of M. Clausius. The author's researches, as here described, tend mainly to confirm this view.

Rendiconti del Reale Istituto, Lombardo, April.—On the importance of the phagociti in the morphology of the Metazoi, by Prof. Leopoldo Magi. The author's researches generally tend to confirm the conclusions of Metschnikoff regarding the physiological functions of the phagociti. He considers that "phagocitism"—that is, the intracellular digestive process—is a function which attests in the morphology of the Metazoi, or pluricellular organisms, their genetic descent from the Protozoi. Thus physiology, as well as embryology and palæontology, confirms the now commonly accepted views regarding biological evolution in animal organisms.

Rivista Scientifico-Industriale, April 30.—On some recent discoveries in electro-optics, by Prof. Ercole Fossati. In connection with the recent researches of Hertz and Hallewachs on the influence of light on electrified conductors, attention is directed to the analogous experiments made by Morichini at the beginning of the present century. Reference is made more particularly to this physicist's observations on the magnetization of steel by the effect of light alone, independently altogether of any action caused by heat or terrestrial magnetism.—Researches on magnetic thermogenesis, by Prof. Giuseppe Martinotti. The experiments described in this and previous papers lead to the general conclusion that heat is developed when soft iron, or any other magnetic body, is successively magnetized; and that the heat is increased by reversing or even simply interrupting the current, which is in accordance with the modern theories on thermodynamics and molecular polarization. But all these experiments are merely preliminary studies in a field of vast and increasing importance, the cultivation of which may ultimately lead to the greatest discovery of modern times, the determination and application of the laws by which the material universe is governed even in phenomena of a psychic order.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 8.—"Contributions to the Anatomy of the Central Nervous System of Vertebrate Animals: Anatomy of the Brain of *Ceratodus forsteri*." By Alfred Sanders, M.R.C.S., F.L.S.

The brain of Ceratodus has the following general arrangement: the membrane which represents the pia mater is of great thickness and toughness; there are two regions where a tela choroidea is developed; one where it covers in the fourth ventricle, and the other where it penetrates through the third ventricle and separates the lateral ventricles from each other.

The thalamencephalon and the mesencephalon are narrow, and the medulla oblongata is wide. The ventricles are all of large size, and the walls of the lateral ventricles are not completed by nervous tissue. All the cranial nerves are to be seen except the abducens and the hypoglossal. There is a large communicating branch between the trifacial and the vagus. The glossopharyngeal has no separate root, but is a branch of the vagus; the ganglion of the vagus is not the termination of the main trunk, but is an off-shoot from the ramus lateralis; the ganglion gives off the branchial nerves and the ramus intestinalis, the ramus lateralis passing on without entering it.

The minute structure of the dorsal part of the cerebrum presents four layers: externally a layer of finely granular neuroglia, with slight indications of radial striation; next a layer of larger-sized cells; then another layer of neuroglia, with fibrillæ having a tendency to a longitudinal direction; and internally a layer of rounded cells closely crowded together. The ventral part of the cerebrum has only two layers, the external of neuroglia, and the internal of rounded cells.

The olfactory lobes resemble the cerebrum in structure, there is an internal layer of cells continuous with those of the cerebrum, and an external layer of glomeruli olfactori, which seem as if they were the external layer of the cerebrum condensed; and between the two, a layer of longitudinal fibres, on which fusiform cells are developed.

The optic lobes also consist of four layers: externally there is a layer of longitudinal fibrils derived from the optic tract; then a layer of smoothly granular neuroglia; then a layer of transverse fibrillæ which collect into a commissure in the central line at the dorsal surface. This layer also contains fusiform and rounded cells sparsely scattered through it; and internally there is a layer of cells mostly rounded. At the central line on the dorsal surface there is a ganglion of large cells resembling those of the optic lobe of the Plagiostomata.

The cerebellum is a mere bridge over the fourth ventricle. Its structure presents the usual number of layers: internally the fibrous layer, which ultimately forms the crura cerebelli ad medullam; then the granular layer, the cells of which are of large size compared to those of the same layer in Teleostei and Plagiostomata; then a layer of Purkinje cells, of which the form and the number of processes are not uniform; externally is the molecular layer, which consists of a coarsely granular network derived from the processes of the Purkinje cells, also a network of finer fibrils and many rounded cells.

In the spinal cord there are three columns of longitudinal fibres on each side in the white substance: viz. the ventral columns between the two ventral roots of the spinal nerves; the lateral columns between the dorsal and ventral roots; and the dorsal columns between the two dorsal roots. Fibres of large size are scattered throughout the two former columns, but collected principally in the ventral. The dorsal consists entirely of minute fibres.

The principal feature in the white substance is a fibre of gigantic size, which is situated on the summit of the ventral columns, one on each side; it consists of a common medullary sheath; inclosing (where the fibre is largest) about 40 to 50 axis-cylinders; these have the character of the axis-cylinders of the ordinary fibres of the white substance, but have no separate medullary sheaths; this fibre is traceable throughout the spinal cord; commencing opposite the posterior end of the abdomen, it extends to a short distance behind the exit of the facial nerve; it varies in size, and becomes of the greatest diameter near the posterior end of the medulla oblongata; its axes escape through the medullary sheath, and join the longitudinal fibres of the ventral columns. Near its anterior termination all the axes have escaped except one; at this point it bears a great resemblance to Mauthner's fibre in the Teleostei. This remaining fibre decussates with that of the other side a short distance behind the exit of the facial nerve, and enters the root of that nerve on the opposite side.

In the gray substance of the spinal cord, there are two series of ganglia, one in the ventral horn, which consists of multipolar cells often of very large size. They send processes into the ventral and lateral columns, which often become the smaller-sized longitudinal fibres. The cells of the other series of ganglia are of smaller size, and are situated in the substantia gelatinosa centralis; they are smooth in outline, and give off one or two processes; they probably have to do with the dorsal roots of the spinal nerves. Cells also of this kind occur at other places, as in the fibræ rectæ, and in the field of the ventral columns.

The transverse commissures are: one in the spinal cord, which passes through the substantia gelatinosa centralis over the central canal; another on the ventral side of the anterior part of the medulla oblongata, which corresponds to the commissura ansulata of the Teleostei, and is connected with the commissure in the dorsal part of the optic lobes; then there is the posterior commissure at the posterior part of the third ventricle; and a commissure at the posterior end of the cerebrum which is the anterior commissure.

There is no chiasma of the optic nerves visible externally; what there is of it, is situated in the substance of the thalamencephalon. The anterior root of the fifth nerve arises from a ganglion occupying a broad swelling at the lateral part of the gray matter of the floor of the fourth ventricle. The posterior root arises from the summit of the restiform bodies.

The facial passes backward in a small tubercle at the junction of the floor of the fourth ventricle with the restiform bodies.

The acusticus arises from a bundle of fibres which are situated on the summit of the ventral column, and appear to be a continuation forward of part of the multi-axial fibre which has not decussated.

The five roots of the vagus pass backward, and enter in succession the same tubercle as, and to the outside of, the facial nerve; the three posterior roots are double, so that the vagus is equivalent to eight nerves, and consists entirely of dorsal roots.

Two nerves are given from the ventral side of the medulla oblongata, each of which has two roots; they do not join the vagus, and pass back some distance within the vertebral canal, and emerge on a level with the exit of the dorsal roots of the spinal nerves.

The second and third spinal nerves supply the pectoral fin, and follow the course usually pursued by the hypoglossal when that nerve is present in Teleostei.

The fibres of the ventral roots of the spinal nerves enter in a direction upward and forward toward the inner edge of the multi-axial fibre, between it and the central canal, and then passing over the dorsal edge of the same are either lost in the gray substance of the ventral horn, join a process of one of the multipolar cells, or become one of the longitudinal fibres of the ventral columns of the cord.

The brain of Ceratodus presents an embryonic condition in three points: viz. first, in the extreme size of the ventricles and the tenuity of the substance of their walls; second, in the alternating origins of the dorsal and ventral roots; third, in the origin of the dorsal roots close to the central line.

Compared to Protopterus, it differs in the shape and imperfection of the cerebral lobes, and in the fact of its having a well-developed rhinencephalon; but it agrees in the narrowness of the mesencephalon, and breadth of the medulla oblongata, and in the rudimentary character of the cerebellum.

Ceratodus agrees also with the Ganoids in the comparative narrowness of the mesencephalon, and in the proportions of the cerebellum.

With the Plagiostomata it agrees in the structure of the optic lobes, both orders presenting a ganglion of large cells in the dorsal part.

With the Teleostei it agrees in the multi-axial fibre, which anterior to its termination resembles the Mauthner's fibre, also in the position and fact of its decussation.

With the Petromyzon it agrees in the structure of the tela choroidea which covers the fourth ventricle.

April 19.—"On the Heating Effects of Electric Currents, No. III." By W. H. Preece, F.R.S.

I have taken a great deal of pains to verify the dimensions of the currents as detailed in my paper read on December 22, 1887, required to fuse different wires of such thicknesses that the law

$$C = ad^{3/2}$$

is strictly followed; and I submit the following as the final values of the constant "a" for the different metals:—

	Inches.	Centimetres.	Millimetres.
Copper	10244	2530	80·0
Aluminium	7585	1873	59·2
Platinum	5172	1277	40·4
German silver	5230	1292	40·8
Platinoid	4750	1173	37·1
Iron	3148	777·4	24·6
Tin	1642	405·5	12·8
Alloy (lead and tin 2 to 1)	1318	325·5	10·3
Lead	1379	340·6	10·8

With these constants I have calculated the two following tables, which I hope will be found of some use and value:—

Table showing the Current in Amperes required to Fuse Wires of Various Sizes and Materials.

$$C = ad^{3/2}.$$

No. S.W.G.	Diameter. Inches.	$d^{3/2}$.	Copper. $a = 10244$.	Aluminium. $a = 7585$.	Platinum. $a = 5172$.	Ger. Silver. $a = 5230$.	Platinoid. $a = 4750$.	Iron. $a = 3148$.	Tin. $a = 1642$.	Tin-Lead Alloy. $a = 1318$.	Lead. $a = 1379$.
14	0·080	0·022627	231·8	171·6	117·0	118·3	107·5	71·22	37·15	29·82	31·20
16	0·064	0·016191	165·8	122·8	83·73	84·68	76·90	50·96	26·58	21·34	22·32

May 17.—"On the Structure of the Electric Organ of *Raia circularis.*" By J. C. Ewart, M.D., Regius Professor of Natural History, University of Edinburgh. Communicated by Prof. J. Burdon Sanderson, F.R.S.

This paper gives an account of the structure of the cup-shaped bodies, which, as mentioned in a previous paper read on April 26, 1888, make up the electric organs of certain members of the skate family. The structure of these electric cups has been already studied in three species of skate, viz. *Raia fullonia*, *R. radiata*, and *R. circularis*. The present paper only deals with the electric organ of *R. circularis*. It shows that the cups in this species are large, well-defined bodies, each resembling somewhat the cup of the familiar "cup and ball." The cup proper, like the disks of *R. batis*, consists of three distinct layers, (1) the lining, which is almost identical with the electric plate of *R. batis*; (2) a thick median striated layer; and (3) an outer or cortical layer. The lining or electric plate is inseparably connected with the terminal branches of the numerous nerve-fibres, which, entering by the wide mouth in front, all but fill the entire cavity of the cup, and ramify over its inner surface, the intervening spaces being occupied by gelatinous tissue. This electric layer, which is richly nucleated, presents nearly as large a surface for the terminations of the electric nerves as the electric plate which covers the disk in *R. batis* and *R. clavata*. The striated layer, as in *R. batis*, consists of numerous lamellæ, which have an extremely contorted appearance, but it differs from the corresponding layer in *R. batis*, in retaining a few corpuscles. The cortical layer very decidedly differs in appearance from the alveolar layer in *R. batis*. It is of considerable thickness, contains large nuclei, and sometimes has short blunt processes projecting from its outer surface. These short processes apparently correspond to the long complex projections which in *R. batis* give rise to an irregular network, and they seem to indicate that the cortical layer of *R. circularis* essentially agrees with the alveolar layer of *R. batis*, differing chiefly in the amount of complexity. Surrounding the cortex there is a thin layer of gelatinous tissue in which capillaries ramify. This tissue evidently represents the thick gelatinous cushion which lies behind the disk in *R. batis*, and fills up the alveoli.

The stem of the cup is usually, if not always, longer than the diameter of the cup. It consists of a core of altered muscular substance, which is surrounded by a thick layer of nucleated protoplasm continuous with the cortical layer of the cup, and apparently also identical with it.

The cups are arranged in oblique rows to form a long, slightly-flattened spindle, which occupies the posterior two-thirds of the tail, being in a skate measuring 27 inches from tip to tip, slightly over 8 inches in length, and nearly a quarter of an inch in width at the widest central portion, but only about 2 lines in thickness.

The posterior three-fifths of the organ lies immediately beneath the skin, and has in contact with its outer surface the nerve of the lateral line. The anterior two-fifths is surrounded by fibres of the outer caudal muscles. It is pointed out that while the organ in *R. circularis* is larger than in *R. radiata*, it is relatively very much smaller than the organ of *R. batis*.

Linnean Society, April 19.—Mr. Carruthers, F.R.S., President, in the chair.—Prof. Martin Duncan exhibited a specimen of *Heterocentrotus mamillatus*, showing the apertures of three of the genital ducts to be in the median interradial sutures, the corresponding basal plates being imperforate. A discussion followed, in which Mr. W. Percy Sladen and Dr. C. Stewart took part.—Mr. George Murray exhibited some specimens of *Spongocladia*, with explanatory coloured diagrams, and made some interesting remarks on the presence of sponge-spicules on Algæ at present unaccounted for.—Mr. D. Morris, of Kew, exhibited, and made remarks upon, the bird-catching sedge, *Uncinia jamaicensis*.—Mr. John R. Jackson, of Kew, exhibited some table mats from Canada made of the highly scented grass *Hierochloa borealis*, and a sample of the so-called pine wool prepared from the leaves of the American long-leaved or turpentine-yielding pine, *Pinus australis*, with a mat made from the wool, an industry which has recently been started on a large scale at Wilmington, North Carolina.—Mr. J. E. Harting exhibited a living specimen of Natterer's bat, which had been captured the previous day at Christchurch, Hants, together with a water-colour drawing from life of Daubenton's bat recently taken at the same place.—The first paper of the evening was by the Rev. George Post (communicated by Mr. Thiselton Dyer), and contained descriptions of new plants from Palestine. In the absence of the author, the salient points in the paper were admirably demonstrated by Mr. J. G. Baker, F.R.S., who exhibited specimens of the plants alluded to.—A paper was then read by the Botanical Secretary, Mr. B. Daydon Jackson, on behalf of Prof. Fream, on the flora of water meadows. An interesting discussion followed, and the meeting adjourned.

May 3.—Dr. John Anderson, F.R.S., Vice-President, in the chair.—The Chairman announced a resolution of the Council to found a gold medal, to be called the "Linnean Medal," to be awarded at the forthcoming anniversary meeting to a botanist and zoologist, and in future years to a botanist and zoologist alternately, commencing with a botanist.—Dr. Francis Day exhibited some specimens of Loch-leven and sea trout raised at Howietoun to illustrate his observation that the markings usually relied upon to distinguish the species are not constant, and therefore, taken alone, of no value for the purpose of identification. He also exhibited specimens of trout from Otago, New Zealand, descendants of some which had been introduced there, presenting some curious modifications of structure. A discussion followed, in which some interesting remarks were made by Prof. Howes and Mr. Willis Bund.—On behalf of Mr. Miller Christy, the Botanical Secretary (Mr. B. Daydon Jackson) exhibited some specimens of the Bardfield oxlip (*Primula elatior*, Jacquin), gathered near Dunmow, and occurring only in this part of England (cf. Trans. Essex Field Club, iii. p. 148).—Mr. A. D. Michael read a paper on the life-histories of the Acari *Glyciphagus domesticus* and *G. spinipes*. After describing in detail observations and dissections extending over three years, the author concludes that there is a hypopial stage in the life-history of *Glyciphagus*, but far less developed than in *Tyroglyphus*, and not an active stage in the species observed; that it does not occur to all individuals of a species, and it has not been ascertained whether it occurs in all species; that the stage is not the result of desiccation or unfavourable conditions; and that it occupies the period between the penultimate ecdysis and that immediately previous. Dr. C. Stewart criticized Mr. Michael's researches in favourable terms.—A communication was then made by Mr. C. B. Clarke on root-pressure. He contested the view of A. Sachs (and his followers) that root-pressure is sufficient to sustain the weight of a column of water of the height of 100 (or even 30) feet, and to force out drops at particular points of the leaves. He maintained that it was a mathematical error to apply the equation $p = g\rho z$ to the case of water in plants, and that in a collection of cells and longitudinal tubes of varying size (all very small) the only mechanical ideas that could be applied were those of capillary attraction and motion. In the discussion which followed, Prof. Marshall Ward thought root-pressure necessary to explain the admitted results of manometer experiments. Mr. A. W. Bennett, on the other hand, regarded the assumption of a high fluid tension in the cells of roots to drive moisture to the summits as nothing more than an expression of our ignorance as to what the water does move.—A paper on the ovicells of some Lichenoporæ was read by the Zoological Secretary (Mr. W. Percy Sladen in the absence of the author, Mr. A. W. Waters.

Physical Society, April 28.—Prof. Reinold, F.R.S., President, in the chair.—The following communications were read:—On electromotive force by contact, by Mr. C. V. Burton. The object of the paper is to discuss the seats of the electromotive forces developed by the contact of conductors. By considering the distribution of electricity on the surfaces of the conductors, and from the fact that the potentials throughout their masses are constant, except about a thin layer near the junction, the author deduces that "*the molecular action which gives rise to a contact E.M.F. between two conductors is confined to the immediate neighbourhood of the junction.*" If E be the contact E.M.F., and M the quantity of electricity which passes across the junction when two metals originally at the same potential are placed in contact, it is shown that the work done is EM, half of which is spent in producing heat and half in raising the potential energy of the system. Since the conductors are supposed to be kept at constant temperature, and the action which gives rise to the E.M.F. is confined to the immediate neighbourhood of the junction, the molecular energy must be absorbed at the junction. By supposing the surface of contact very small, and the capacity of the system large, it is shown that *heat* and *chemical action* are the only kinds of energy which fulfil the required conditions of supplying an indefinite amount of energy. Hence, for substances chemically inactive, "*the true contact E.M.F. is equal to their coefficient of the Peltier effect* *expressed in absolute measure*"; and for substances chemically active, but devoid of Peltier effect, "*the E.M.F. is equal to the energy of combination of one electro-chemical equivalent.*" Since metal-metal contacts can only be the seats of Peltier E.M.F.'s it is inferred that the apparent contact E.M.F. (measured inductively) must be due chiefly to air-metal contacts. A list of analogous properties of Peltier and chemical E.M.F.'s is given in parallel columns. The results of some experiments on the contact E.M.F. of glass and ebonite with mercury are tabulated, but they are very irregular, and the author concludes that there is no true and definite contact E.M.F. between conductors and non-conductors. Profs. Ayrton, Schuster, Thompson, and Perry discussed the points raised, and it was considered that direct experiment on contact E.M.F. in a very perfect vacuum could alone decide the questions.—On a theory concerning the sudden loss of magnetic properties of iron and nickel, by Mr. H. Tomlinson. Experiments by himself and other observers have shown that the temperatures at which iron and nickel lose their magnetic properties depend on the specimens used, and the magnetizing forces employed; but the temperature at which they *begin to lose* these properties are definite—for nickel about 300° C., and iron about 680° C. The author's own experiments on "Recalescence of iron" show two critical temperatures; and Pinchon has shown by calorimetric measurements that between 660° and 720° C., and between 1000° and 1050° C., heat becomes latent. All these facts seem to indicate a molecular rearrangement about these temperatures. In his proposed theory, he assumes that the molecules of iron (say) contain magnetic atoms capable of motions of translation and of rotation. These tend to form closed magnetic circuits, but at ordinary temperatures are unable to do so on account of the close proximity of their centres. On raising the temperature, their centres are further separated till at about 680° C. their polar extremities rush together, forming complete circuits and exhibiting no external magnetic properties. On cooling down, the centres approach until the gravitation attraction overcomes the magnetic attraction of their poles, when the magnetic properties reappear. Prof. Ayrton asked whether the author had made experiments on the reappearance of magnetic properties when raised to a white heat, and Prof. Thompson inquired whether cobalt had been tested. Both questions were answered negatively.—Note on the graphic treatment of the Lamont-Frolich formula for induced magnetism, by Prof. S. P. Thompson. The formula referred to is $N = \bar{N}\,\frac{Si}{Si+b}$; where $\bar{N}$ = total induction when saturated, N = induction due to Si ampere turns, and b = value of Si which makes $N = \frac{1}{2}\bar{N}$. Simple geometrical constructions are given for plotting the curve when $\bar{N}$ and b are known, and for finding $\bar{N}$ and b when two pairs of values of N and Si have been determined. The use of the formula is shown to be justified in practice, for, as pointed out to the author by Prof. Perry, the curves connecting permeability, μ, and induction, B, are straight lines from B = 7000 to B = 16,000, between which dynamos are usually worked. A method of predetermining $\bar{N}$ and b is given for magnetic circuits of known form and materials, thus removing the objection often urged against the above formula, viz. that it involves two constants which had to be determined after the magnet was made.

Mathematical Society, May 10.—Sir J. Cockle, F.R.S., President, in the chair.—Mr. E. B. Elliott communicated a fourth paper on cyclicants or ternary reciprocants and allied functions.—Mr. Cook Wilson gave a sketch of some theorems on parallel straight lines, together with some attempts to prove Euclid's twelfth axiom. Messrs. Elliott, Buchheim, and Prof. Henrici, F.R.S., took part in a lengthened discussion of the paper.—The following were taken as read:—On the flexure and the vibrations of a curved bar, by Prof. H. Lamb, F.R.S.—On the figures formed by the intercepts of a system of straight lines in a plane and on analogous relations in space of three dimensions, by S. Roberts, F.R.S.—On Lamé's differential equation; and stability of orbits, by Prof. Greenhill.

Entomological Society, May 2.—Dr. D. Sharp, President, in the chair.—Dr. P. B. Mason exhibited an hermaphrodite specimen of *Saturnia carpini*, from Lincoln, and another specimen of the same species with five wings, bred at Tenby.—Herr Jacoby exhibited female specimens of *Chrysomela japana*, collected by Mr. J. H. Leech in Japan, and called attention to a sexual structure in the middle of the abdominal segment.—Mr. Adkin exhibited a variety of *Eubolia bipunctaria*, taken at Box Hill.—Mr. W. F. Kirby exhibited, for Dr. Livett, a curious discoloured female specimen of *Ornithoptera minos*, Cramer.—Mr. H. Goss exhibited, for Mr. W. Denison-Roebuck, a number of specimens of an exotic species of bee obtained by the Rev. W. Fowler, of Liversedge, from split logwood. The cells or pouches were very irregular and rough, and altogether unlike those of any known British species.—Dr. J. W. Ellis read a paper entitled "Remarks on the British Specimens of *Aphodius melanostictus*, Schmidt," and he exhibited a number of specimens and drawings of this species and of *Aphodius inquinatus*, F. A discussion ensued, in which Dr. P. B. Mason, Dr. Sharp, Mr. Champion, and Dr. Ellis took part.—Mr. E. Meyrick communicated a paper on the Pyralidina of the Hawaiian Islands, the material for which paper consisted principally of the collection of Lepidoptera Heterocera formed by the Rev. T. Blackburn during six years' residence in the Hawaiian Islands. Mr. Meyrick pointed out that the exceptional position of these islands renders an accurate knowledge of their fauna a subject of great interest. He stated that, of the fifty-six known species of Hawaiian Pyralidina, nine had probably been introduced through the agency of man in recent times; but he believed the remaining forty-seven to be wholly endemic: of these latter the author referred twenty-six species to the *Botydidæ*, twelve to the *Scopariadæ*, four to the *Pterophoridæ*, three to the *Crambidæ*, and two to the *Phycitidæ*. Dr. Sharp, Mr. McLachlan, Dr. Mason, and Mr. E. B. Poulton took part in the discussion which ensued.

PARIS.

Academy of Sciences, May 14.—M. Janssen, President, in the chair.—On diamagnetism, by M. Mascart. In connection with M. Blondlot's recent communication describing an experiment on the apparent diamagnetism of a solution of the perchloride of iron in a more concentrated solution of the same substance, it is pointed out that in 1845 Faraday showed that the action of the magnetic forces on a body depends on the medium in which it is plunged, as it results from the difference of their coefficients of magnetic induction. If the intensity of magnetization remains proportional to the magnetizing force, which is the case with all diamagnetic and slightly magnetic bodies, the theory then shows that the magnetizm on the surface of the body in question changes its sign when the outer medium has a high coefficient.—Remarks accompanying the presentation of a map of Massaya in Abyssinia, by M. d'Abbadie. Attention was drawn to some cartographic improvements introduced into this map by the author with the view of rendering the nomenclature more distinct, and more in accordance with the local pronunciation of geographical names. In all cases such foreign descriptive terms as *Ras*, *Jebel*, &c., give place to their equivalents *Cape*, *Mount*, &c.—Fluorescence of cupriferous lime, by M. Lecoq de Boisbaudran. After calcination in the air, carbonate of lime containing a little oxide of copper yields a substances which gives in vacuum an extremely bright green fluorescence. No spectral rays have been observed. When calcination takes place in hydrogen, instead of the green fluorescence, a more or less pink or reddish light is obtained, at times somewhat intense, but always greatly inferior to the green fluorescence.—Observations of the new planet 277, discovered on May 3, at the Observatory of Nice, by M. Charlois. The observations extend over the period from May 3 to May 9, when the planet appeared to be of the thirteenth magnitude.—Observations of the same planet are recorded for the period May 5–12, taken by M. Trépied, at the Observatory of Algiers.—Observations of the channels in Mars, by M. Perrotin. Some important modifications are described, that have taken place in these appearances since they were first observed by the author in 1886. The triangular continent, somewhat larger than France (the Lybia of Schiaparelli's map), which at that time stretched along both sides of the equator, and which was bounded south and west by a sea, north and east by channels, has disappeared. The place where it stood, as indicated by the reddish-white tint of land, now shows the black, or rather deep blue colour of the seas of Mars. The Lake Mœris, situated on one of the channels, has also vanished, and a new channel, about 20° long and 1° or 1°·5 broad, is now visible, running parallel with the equator to the north of the vanished continent. This channel forms a direct continuation of a previously existing double channel, which it now connects with the sea. Another change is the unexpected appearance about the north pole of another passage, which seems to connect two neighbouring seas through the polar ice.—Action of hydrochloric acid on the solubility of stannous chloride; hydrochlorate of stannous chloride, by M.

Engel. It is generally assumed that the solubility of stannous chloride in water increases in the presence of hydrochloric acid. But the experiments here described show that this is the case only when the quantity of acid added to the saturated solution of the chloride attains a certain value. The hydrochlorate of stannous chloride, here also described, has for formula, $SnCl_2 + HCl_2 + 3H_2O$. It crystallizes and melts at about $-27°$.—On the existence of a pyrophosphorous acid, by M. L. Amat. The existence here demonstrated of this body is a brilliant verification of the theory of Wurtz regarding the constitution of the phosphorous and hypophosphorous acids.—Essay on the equivalents of the simple bodies, by M. Delauney. Taking as unity the equivalent of hydrogen, the equivalents of the simple bodies may be obtained by the expression, $\frac{N}{3}\sqrt{5^2 - n^2}$, where N and n are integers, the values of n being obviously restricted to 0, 1, 2, 3, or 4. According to these several values of n the elementary bodies are disposed in so many family groups, from which chlorine alone is excluded, while its neighbour, bromine, appears to belong to as many as three of the groups. This classification seems natural, the first family supplying the true metals—copper, gold, lead—below which, in the descending scale, the fifth family corresponds to the alkaline metals and metalloids. From all this is deduced a curious molecular theory based on the assumption of a primitive molecule formed of six atoms. Around one of these the other five describe circles with radii 1, 2, 3, 4, 5, all moving in the same plane, and the central atom revolving round its own axis perpendicular to the plane. The atoms at the distances 1, 2, 3, 4 revolve in the same direction as the central, the outer in the contrary direction, the molecule thus constituting a sort of astronomic system, infinitely small, but analogous to the stellar groups. All these considerations go to confirm in principle, if not in fact, the views of those chemists who hold that all the simple bodies are ultimately reducible to one—that is, hydrogen.—Researches on the synthesis of the albuminoid and proteic substances, by M. P. Schutzenberger. Having completed his analytical studies of albumen, fibrine, caseine, gelatine, and other proteic substances, the author has now begun the study of their synthesis. In this paper the first results are given, showing that the leuceine obtained by the synthetic process is identical with that yielded by decomposition.

BERLIN.

Physiological Society, April 27.—Prof. du Bois-Reymond, President, in the chair.—Dr. Blaschko spoke on the development of horny tissue. Between the rete Malpighii and the corneous layer (stratum corneum) of the epidermis two layers are found—the stratum granulosum and the stratum lucidum—in which the cells of the rete, produced karyokinetically, must undergo their conversion into the epidermal cells of the stratum corneum. The speaker confined himself first to a consideration of the granules of the stratum granulosum, about which most widely different views have been advanced by various writers. They have been regarded as consisting of fat, cholesterin, amyloid substance, proteid, keratin, and hyalin; and further as fluid, semi-fluid, or solid. Dr. Blaschko has satisfied himself that the granules are not fluid, but that they contain more water than the cells of the epidermis. He has further proved by employing all the chemical reactions which are characteristic of such different substances as fat, cholesterin, proteid, &c., that the granules cannot be regarded as composed of any of the above. The curious colour they assume when stained with hæmatoxylin, and their behaviour with chemical reagents, shows that their proper place is one intermediate between albumen and keratin; the speaker hence proposed to give the name of prokeratin to the material of which the granules are composed.—Dr. Klaatsch had made a series of preparations from the skin of monkeys, by which he shows that it is possible, by using various colouring-matters, to give different colours to the stratum lucidum and stratum corneum in one and the same specimen, thus making it easy to distinguish these layers each from the other and from the stratum granulosum. He shows further that in the skin of monkeys, as in that of man, alternating elevations and depressions are met with; the former, or gland-hillocks, cover the glands of the skin, while the latter, or folds, are joined by tense bundles of connective-tissue passing through the rete, and thus forming an attachment for the skin. Finally, and in the third place, the preparations showed that the nuclei of the cells in the rete are still here and there recognizable in the stratum corneum as spaces which are probably formed by a disappearance of the nuclear substance, the nuclear membrane being persistent.—Dr. R. Schneider has carried on a series of researches, extending over nearly every class of animals, on the absorption of iron and on its occurrence as oxide in the organs and tissues of the animals. Up to the present time all the animals examined, whether living in water, mud, or underground, have contained oxide of iron; which was detected, using all due precautions, by employing ferrocyanide of potassium and dilute hydrochloric acid. The speaker gave an account of the behaviour of single animals taken from the Protozoa, Cœlenterates, Worms, Arthropods, Gasteropods, Fishes, and Amphibia. Among Vertebrates, oxide of iron was found in the cells of the alimentary canal, in the liver and spleen, occasionally in the kidneys and teeth, and in Proteus it occurred throughout the whole skeleton. Among the Invertebrates oxide of iron was found to occur in the cells of the liver and intestine, in the respiratory organs, the shells and chitinous envelopes. The oxide occurred chiefly in the protoplasm of the cells, but also frequently in the nuclei. It is impossible here to enlarge further upon the interesting details of which Dr. Schneider supplied an extended series.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Theoretische Geologie: Dr. E. Reyer (E. Schweizerbachsche).—Practical Lessons in the Use of English: M. F. Hyde (Heath, Boston).—The Origin of Floral Structures: Rev. G. AL-BÎRÛNÎ.

Al-Bîrûnî's India: an Account of the Religion, Philosophy, Literature, Chronology, Astronomy, Customs, Law, and Astrology of India about A.D. 1030. Edited in the Arabian original by Dr. Edward Sachau. (London: Trübner and Co., 1887.)

IT has often been said that India has no history and no historians. We look in vain through the ancient Sanskrit literature for any Herodotus or Thucydides. The very idea of chronicling the events of the day or gathering the recollections of the past seems never to have entered the Hindu mind, and their ancient chronology is hardly more than astronomical mythology. The historical growth of Indian literature, religion, and philosophy would indeed have remained a perfect riddle but for the few glimpses which we are able to catch of the real history of the country through other nations which were brought in contact with it. These are the Greeks, the Chinese, and the Arabs, whose successive accounts run like three broad bands of longitude across the ill-defined map of ancient India.

The Greeks do not tell us very much of what they saw of India, either before or after Alexander's invasion. We may indeed gather from Hecatæus (B.C. 549-486) that India existed, and that its chief river, the Indus, had a name of Sanskrit origin. We know, therefore, that Sanskrit was the spoken language of India in the sixth century B.C. But even that name had clearly passed through Persian channels before it reached Hecatæus, for it is only in Persian that the initial *s* of *Sindhu*, the river, could have been changed into *h*, and afterwards been dropped. Herodotus also mentions some Indian names—such as the *Gandarii*, the *Gandhâras* of the Veda—which clearly show that at his time the peoples and rivers and mountains of India had names which find their explanation in Sanskrit only. With Alexander's expedition we might have hoped that the full light of history would have burst upon India. But most of the works written by Alexander's companions have been lost, and even the work of Megasthenes, who stayed as ambassador at Palimbothra, the modern Patna, at the court of King Sandracottus, has been preserved to us in fragments only. Still the date of Sandracottus, in Sanskrit Chandragupta, has proved the sheet-anchor of ancient Indian chronology, and has once for all fixed the date of Chandragupta and of his grandson, the great Buddhist monarch Asoka, in the fourth and third centuries B.C.

The next witnesses to the actual state of political, social, and religious life in India are the Chinese. Buddhism had been adopted as a third State religion in China in the first century A.D. From that time the religious intercourse between China and India was never entirely interrupted. Buddhist priests travelled from India to China, and pious pilgrims went from China to India as the holy land of their religion. Some of these pilgrims have left very full descriptions of what they saw and did in India, the most important being those by Fa-hian (399-414 A.D.), Hiouen-thsang (629-645), I-tsing (673-695), and Khi-nie, who visited India in 964, at the head of 300 pilgrims. Most of these travels and diaries have been translated into French and English by Remusat, Stanislas Julien, Beal, and Legge; and they give us a picture of Indian life during the Middle Ages of which we should have had no idea if we had been restricted to Indian sources alone.

More important, however, than the descriptions of these Greek and Chinese authors, is the work to which we wish to call attention—namely, the account of India written by Al-Bîrûnî in the year 1030 A.D., and now published for the first time by Prof. Sachau, of Berlin. Al-Bîrûnî was a native of Khwârizm, the modern Khiva, born in 973. He had devoted himself to the study of astronomy and philosophy, and when Khiva was taken by Sultân Mahmûd of Ghazna in 1017, Al-Bîrûnî was induced to accompany him to India. The famous Avicenna, *i.e.* Abu Ali Ibn Sina, declined the same honour, and remained at home. During the thirteen years that Al-Bîrûnî spent in India, he devoted himself sedulously to the study of Sanskrit, and Sanskrit literature. He does not use the name of Sanskrit, but calls the language of India, both literary and vernacular, Hindi, *i.e.* Indian; the fact being that Sanskrit was not yet used as a proper name of the ancient literary idiom, but only as an *epitheton ornans*. What progress Al-Bîrûnî made in his studies seems somewhat doubtful. It was formerly supposed that he translated not only from Sanskrit into Arabic and Persian, but likewise from Arabic and Persian into Sanskrit. But Dr. Sachau has clearly proved that his knowledge of Sanskrit was far too elementary to enable him to perform such tasks by himself. He shows that he depended chiefly on the assistance of his pandits, like many Sanskrit scholars of more recent times, and that all we can assert with safety is that he was able to direct and to check their labours. With all that, Al-Bîrûnî was a most exceptional man for his time, a man of wide sympathies, a true philosopher, and acute observer. The very idea of learning a foreign language, except perhaps Persian and Turkish, never entered the head of a Muhammedan. His weapon was the sword, not the pen. Al-Bîrûnî, however, to quote Prof. Sachau's words, "convinced that those who want to meet the Hindus on the battle-ground of intellectual warfare, and to deal with them in the spirit of justice and equity, must first learn all that is peculiar to them in manners and customs as well as in their general modes of thought, produced a comprehensive description of Indian civilization, always struggling to grasp its very essence, and depicting it with due lights and shades, as an impartial spectator." The title of the book tells its own story: "*An accurate description of all the categories of Indian thought, as well those which are admissible, as those which must be rejected.*"

The existence of this work of Al-Bîrûnî's has been known for many years, and Sanskrit scholars have long clamoured for its publication and translation. Their appetite was first whetted by the specimens which Reinaud published in 1845 in his "Fragments Arabes et Persans relatifs à l'Inde," and some years later in his invaluable "Mémoire sur l'Inde" (1849). When Reinaud declined to undertake the editing of the whole text of Al-Bîrûnî's "Indica," Woepcke and MacGuckin de Slane undertook the difficult task. The former, however, died;

the latter began to feel the approach of old age, and the prospect of a speedy termination of this important undertaking became more and more doubtful, when, in the year 1872, a young German scholar, Dr. Sachau, boldly stepped into the breach, and promised to devote all his time to this great enterprise. After fifteen years of hard work he has redeemed his pledge. He has given us the Arabic text of Al-Bîrûnî, and he is now engaged in printing an English translation of it. We doubt whether anyone could have been found so well qualified for the task. Dr. Sachau has long been known as a hard-working, honest, and thoroughly sound scholar. He stands in the first rank among the students of Arabic and Persian, and he possesses, at the same time, a fair knowledge of Sanskrit. He is now one of the brightest stars in the University of Berlin, and has lately been appointed there as Director of the newly-founded Imperial School of Oriental Languages. He was well prepared for his task by having previously published another work of Al-Bîrûnî's, the text and English translation of "The Chronology of Ancient Oriental Nations." Few people can appreciate the enormous difficulties of publishing for the first time an Oriental text like that of Al-Bîrûnî. Dr. Sachau was, no doubt, more fortunate than his predecessors in securing a manuscript of Al-Bîrûnî's, belonging to M. Schefer, which professes to have been copied from a copy in the handwriting of the author. But even thus the labour of editing and translating such a text, which had never been edited and translated before, was enormous. When speaking of the difficulties which he had to overcome in editing Al-Bîrûnî's chronological work, Dr. Sachau writes: "I have boldly attacked the sometimes rather enigmatic style of the author, and if I have missed the mark, if the bewildering variety and multiplicity of the subject-matter have prevented my reaching the very bottom of every question, I must do what more or less every Oriental author does at the end of his work —humbly ask the gentle reader to pardon my error and correct it." There is the true ring of the *bonâ fide* scholar in this. No one is nowadays considered a real Oriental scholar who has not won his spurs by an *editio princeps*. After a text has once been constituted by a comparison of manuscripts more or less faulty; after a translation has once been accomplished, however imperfect, it is easy enough to print a new so-called critical edition, or a new so-called improved translation. But the scholars who take the first, and the scholars who take the second, step belong to different races. They differ as Columbus who discovered America differs from the traveller who now crosses the Atlantic in seven days. "Generations of scholars," as Dr. Sachau says, "have toiled to carry the understanding of Herodotus to that point where it now is, and how much is wanting still!" To expect, therefore, that Al-Bîrûnî's text, as edited here for the first time, or its translation, should be free from mistakes would only show a complete ignorance of the conditions under which Oriental scholars have to work. There may be hereafter better editions of Al-Bîrûnî; there never can be one so creditable to its author as this *editio princeps*. We could have wished that a work of such importance to students of Indian history had been carried out by an English scholar. But, failing that, we have at least the satisfaction that the expense of publishing the Arabic original of the "Indica" has been generously defrayed by the Indian Government, following in this respect the noble example set by the patron of Al-Bîrûnî himself, the powerful Sultân Mahmûd of Ghazna.

THE SCIENTIFIC WRITINGS OF JOSEPH HENRY.

The Scientific Writings of Joseph Henry. Two Vols. 8vo, pp. 1082. (Washington: Smithsonian Institution, 1886.)

UNDER the above title, two handsome volumes have recently been published by the Smithsonian Institution, Washington, containing the papers published by its late distinguished Secretary in various scientific serials through the long period of fifty-four years. It is characteristic of the man that, although for thirty-two of those years he had almost unrestricted command of the publishing resources of that great institution, not one of his papers was given to the world through the medium of the "Smithsonian Contributions" or "Miscellaneous Collections," or in any way at the expense of its funds. They range over a great variety of subjects, chiefly in electrical physics and meteorology, and in date from 1824 to 1878.

As may be inferred from the earlier of these dates, when Faraday was still an assistant to Sir Humphry Davy, in the laboratory of the Royal Institution, and Henry a private tutor in a family at Albany, New York, many of these papers are reprinted for their historical interest rather than for their present scientific value; but his fellow-countrymen, in acknowledging Faraday's preeminence, delight to point out in how many particulars Henry walked *pari passu* with him in the then nearly untrodden paths of electro-magnetism, under immense relative disadvantages. As early as 1835, Henry, then a Professor at Princeton, New Jersey, connected his residence with his laboratory in the Philosophic Hall by a telegraph, in which the galvanic circuit was completed through the earth—probably the first realization of that familiar property on which all our telegraph circuits are now dependent. It was a little later (in 1842) that he showed the writer of this short notice, under promise of secrecy, an experiment which at the moment greatly interested him. A long bar of iron was wrapped in a coil or ribbon of copper, half an inch wide; two copper wires, each terminating in a small ball, were soldered to the bar. On holding these balls to the ears, and transmitting a strong current through the coil, a very distinct musical note was heard each time the current was made or broken. He narrowly missed forestalling Faraday in the great discovery of producing electric currents by the rotation of an electro-magnet or movement of its armature. Henry caused an electro-magnet of unusual power to be constructed in August 1831, with a view to realizing his conceptions on this subject. He was at the time accidentally interrupted in pursuing his experiments, and did not resume them until May or June 1832; and in the meantime (in February 1832) Faraday had made his independent discovery.[1] As early as 1843, Henry proposed "a new method of applying the instantaneous transmission of an electrical action to determine the time of the passage of a (cannon) ball between two screens, placed

[1] *Philosophical Magazine*, April 1832.

at a short distance from another in the path of the projectile," and contrived a self-recording apparatus reading to the one-thousandth part of a second. As at that time Hutton and the ballistic pendulum reigned supreme—and this is not an experiment easily made in a laboratory—it does not appear that he carried it out. Perhaps the most elaborate of his numerous researches is that on the transmission of sound in relation to fog-signalling, carried on at the expense of the United States Lighthouse Board for several years from 1865 onwards, concurrently with those on which Prof. Tyndall was at that time engaged for the Trinity Board. That these distinguished men did not always meet with the same effects, or draw the same conclusions from them, is but a natural consequence from the extreme complexity of the phenomena.

The great work of Prof. Joseph Henry's life—in which his strength and calmness of judgment, his high-minded independence and self-effacement, enabled him to achieve the highest results—was the organization of the Smithsonian Institution upon its present liberal basis, in the face of not a little opposition from persons of more contracted views.

"These I's are *egos*, and not *oculi*," is a line from some forgotten squib which he was wont to quote when self-interest seemed to obscure the only interest precious to him—that of science in its widest scope, and the advancement of human knowledge. He lived to see the wisdom of his policy gratefully acknowledged by his countrymen and the scientific world. Although a very fertile inventor, and the author of many ingenious contrivances now in use to facilitate the working of the electric telegraph, he never patented anything. In his own words, he "did not consider it compatible with the dignity of science to confine the benefits which might be derived from it to the exclusive use of any individual." The expression is not carefully chosen; it simply means that he declined to derive selfish advantage from his discoveries. A very brief and modest statement by himself of what these were in relation to the electro-magnetic telegraph is reprinted in vol. ii. from the Smithsonian Annual Report for 1857. In collecting and reprinting these papers, the Institution has raised a worthy monument to Henry's memory, and made a valuable contribution to the history of physical science.

J. H. L.

AN ELEMENTARY TEXT-BOOK OF PHYSIOLOGY.

An Elementary Text-book of Physiology. By J. McGregor Robertson, M.A., M.B., Senior Assistant in the Physiological Department, University of Glasgow. 350 pp. (London: Blackie and Son, 1887.)

IN compiling this volume the author has sought to "present the essential facts and principles of physiology, not in a series of disconnected paragraphs, but woven into a continuous story." This being so, we look for a readable book rather than for the more empirical treatise nowadays predominant; and the the success of the work must consequently depend, in the main, upon the manner in which the narrative is strung together. That the book really is a readable one there can be no doubt, and for style and general accuracy it is very satisfactory. When we consider the method of arrangement adopted, however, we must confess that it is disappointing. The author lays it down as a tenet that "we cannot properly understand the physiology of the human body without reference to the form and build, . . . and thus we shall have to note the main anatomical facts regarding a part of the body before going on to consider the work which that part does." Very proper, and true to the letter. In spite of this, however, the reader is led straight away into a consideration of the chemical constitution of the body as a whole. Surely it would be more logical to treat of the constitution of the several structural elements in order of presentation, deferring the more general statements for a final *résumé*. A similarly dangerous position is approached when the writer deals with structure itself. Chapter II. is devoted to "Elementary Structures," that is to say, the author discusses the structural unit before entering upon a consideration of those organs and tissues which are its aggregates. This is an old grievance, and all experience shows that this method, though at first sight apparently natural, is in reality seductive, if not illogical. It is fair to the author to state that he does not adopt it throughout. In view of it, however, the following statements are the more unfortunate: "cells are little masses of a jelly-like material"; "usually the cell has an outer covering or membrane, called the *cell-wall*"; "from little nucleated masses of protoplasm cells are produced, and then from cells all the other textures of the body are derived."

As the work is of a readable character, we expect, furthermore, to find comparisons and illustrations drawn from the experience of daily life, and in this we are not disappointed. Stock comparisons, like that of the human body with the steam-engine, come in as a matter of course, and in his choice of novel ones the author has been very successful. Nothing can, however, be more easily overdone than this. If, for example, the human eye is compared with the photographer's camera, care ought to be taken to point out in what the two differ, especially when considering the lens in accommodation. This has not been done.

Taking the book as a whole, the author is to be congratulated, and especially so upon his treatment of certain leading topics—notably that of diet. By far the weakest parts of the work are those devoted to histology. The interminable striped muscle question is most feebly treated, and who but the author is to know what is meant by the words "the nerve-tubes end, it has been seen, in the (muscle) fibres"? The description of a secreting gland generally given is so worded as to imply that the "basement membrane" is a leading, if not the chief, constituent thereof. These and other defects referred to in the sequel demand immediate attention, and we would fain see the elimination of such old heresies as the capillary or "hair-like vessel" and the transmission of "messages" along the nerve-fibre. There would appear to be a fatality in the persistency with which teachers of a certain class continue to thrust these and similar stumbling-blocks in the way.

This volume is confessedly designed for the "requirements of candidates for the examinations of the Science and Art Department and of the Local Examination

Boards of the Universities," and the syllabus of the first-named body is appended to it. The book thus finds a place among the legion of cram-books which now threaten to overwhelm us. The majority of these are, as everybody knows, notoriously bad, and readers of NATURE will not need to be reminded that strong measures are being proposed for the purpose of checking the evil consequent upon their multiplication, and that of elementary text-books in general. Conspicuous among these is the recent proposal to establish a Publication Committee, whose members shall sit in judgment on all text-books, with power to suppress or modify at will. With this suggestion we have no sympathy: it is unscientific in principle, while its adoption would tend towards the establishment of a conservatism and narrow cliquism greatly to be dreaded. The introduction of such a measure would, in our opinion, only serve to strengthen that spirit of popery which threatens to invade certain branches of science in our own lands. The evil will assuredly work it's own end, and, so far as professed cram-books are concerned, the publication of works of such relatively general excellence as the one before us cannot fail to be a far more potent remedy—a more natural one it most certainly is.

Chief among the defects referred to above, as standing in need of revision, are the following. Too little importance is throughout attached to the sources and evolution of heat in the animal economy; the parts played by the muscles and liver need especial comment, and we note that in the table of gains and losses given no count is taken thereof. The functional importance of the diaphragm in the mechanism of respiration is over-stated; on the other hand, that of the withdrawal of water by the kidney is under-stated as a fundamental of excretion. The distribution and function of glycogen are insufficiently noted. The references to non-nucleated cells (p. 26), and to the comparative anatomy of the central nervous system, might well be excised; while the long *résumé* (pp. 255–58) of brain-functions given might be advantageously replaced by a more concise description of the actual facts determinable in a typical case. The relegation (p. 48) of the sutures of the cranial bones to the category of "imperfect joints" is groundless.

Numerous illustrations are employed, and of these many are new and highly satisfactory. Figs. 42, 45, 80, and 118, are, however, little short of useless. It is a fact, and not a "*view*," that "the life of the body is the sum of the lives of the individual cells composing it," and it cannot be said that with the study of the anatomy of the lungs we begin our "*view*" of the means of purification of the blood.

OUR BOOK SHELF.

Evolution and its Relation to Religious Thought. By Joseph Le Conte, Professor of Geology and Natural History in the University of California. (New York: D. Appleton; London: Chapman and Hall, 1888.)

THE title of this book is somewhat misleading. The work is in effect a concise account of evolution and its principal evidences, contained in 253 pages, supplemented by 82 pages giving the author's views on the relation of evolution to materialism, which he rejects, and to several religious questions, of which we can only say in these columns that they are dealt with in a candid spirit, on the basis that the law of evolution is thoroughly established, and is indeed "a necessary condition of rational thought." The exposition of evolution is well-planned, the main problems and their significance and the modes of proof being clearly and simply set out, so that the general reader with a modicum of knowledge of natural history may realize them to a considerable extent. These chapters are illustrated by a number of well-selected comparative figures, such as the fore and hind limbs of typical vertebrates, the evolution of the horse family, and the vascular system and brain of vertebrates. Prof. Le Conte cordially accepts Mr. Romanes's "physiological selection" as the most important advance in the theory of evolution since Darwin; and it is significant that this new view should have already found a place in a popular work written by a man of science. It is, however, a little hazardous to apply with so much confidence a theory still requiring proof; and this appears to lead the author to put forward a still less proven idea, not new it is true, that the steps of evolution at certain times become comparatively rapid, so that there may be few generations, or perhaps only one, between successive species. Some of the author's statements are undesirably broad, as when he says, "All vertebrates, and none other, have a number of their anterior vertebral joints enlarged and consolidated into a box to form the skull, in order to inclose and protect a similar enlargement of the nervous centre, viz. the brain." Of course the author is excluding Amphioxus, but he does not say so. Similarly the statement that "by extensive comparison in the taxonomic and ontogenic series the whole vertebrate structure in all its details in different animals may be shown to be modifications one of another" is a little vague. But on the whole the book is sufficiently accurate, and should prove useful.

Outlines of Qualitative Analysis. By George W. Slatter, Science Master at the Salt Schools, Shipley. (London: Thomas Murby, 1888.)

THIS further addition to the already large number of books on elementary analysis is compiled from the author's laboratory notes issued to his students in the Salt Schools. Most teachers appear to have a few particular methods of their own, and the custom of writing a book to embody them seems to be fast gaining ground. With the matter of Mr. Slatter's book one can find very little fault; but at the same time, except for the use of his own students, one can scarcely see any reason why another book should be presented to the public, when all the facts, in a much more complete form, are already given in most of the larger laboratory guides now in vogue.

The majority of the methods recommended are certainly well-tried and convenient ones; and a very good point is the trouble taken in explaining the theory of the analysis tables. Exception, however, may be taken to Mr. Slatter's mode of separating antimony and tin by use of Marsh's apparatus: while theoretically good, experience shows that accidents are liable to happen, and this is especially the case among young students; hence the platinum and zinc electrolytic method is more frequently preferred. The author seems also to have a predilection for the use of nitro-hydrochloric acid in dissolving the sulphides of nickel and cobalt in Group III., while there can be no doubt that potassium chlorate and hydrochloric acid work far better, there being no danger of leaving nitrates in the solution.

The method of analyzing phosphates is one which works very well, and is probably the best known. Similarly the analysis of double cyanides by ignition with ammonium nitrate and sulphate is the one which in the writer's opinion is both the simplest and gives most satisfactory results.

A. E. T.

The Land of the Pink Pearl. By L. D. Powles. (London: Sampson Low, 1888.)

MR. POWLES served for some time as a circuit justice in the Bahama Islands, and in the present volume he communicates the impressions produced upon him both by the islands themselves and by their inhabitants. He makes no profession of an intimate knowledge of any branch of science, so that the work contains few elements of interest that call here for special notice. We may say, however, that the book is written in a lively and agreeable style, and that the author has brought together much useful general information about what he calls "this obscure corner of Her Majesty's dominions." The most valuable passages are those in which he deals with the relations between the white and the coloured population. His statements on this subject are certainly not lacking in vigour, for he speaks of the African race in the Bahamas as being "ground down and oppressed in a manner which is a disgrace to British rule." When Mr. Powles went to the Bahamas, he had an impression that negroes were "intended by Nature to be kept in subjection by the whites." Experience, however, led him to modify this extravagant notion. Referring to the statement, so often made, that "it is impossible to produce anything by free negro labour," he sensibly suggests that "perhaps if the Imperial Government would establish an agricultural college and give the coloured race in the Bahamas a fair chance, we might see a different state of things." The physical deterioration of the coloured people is, he thinks, sufficiently accounted for by their wretched food and by the unhealthy nature of the places in which they are compelled to live. Curiously enough, Africans in the Bahamas retain their original tribal distinctions; and Mr. Powles says that every August some tribes elect a queen whose will on certain matters is accepted as law.

A Treatise on Alcohol, with Tables of Spirit-Gravities. By Thomas Stevenson, M.D. Second Edition. (London: Gurney and Jackson, 1888.)

THE present edition of this useful little work, originally published under the title of "Spirit-Gravities," contains a critical account of the various determinations of the specific gravity of alcohol, and introduces the most recent investigations—those of Messrs. Squibb—on this subject. These investigations do not, however, affect the accuracy of the alcoholometric tables, which are therefore reprinted unchanged.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Dispersal of Seeds by Birds.

IT should be borne in mind by readers of NATURE in various parts of the world that many facts bearing on this matter may be collected with very little trouble. At Mr. Thiselton Dyer's suggestion I take this opportunity of supplementing my letter to Mr. Botting Hemsley (NATURE, vol. xxxviii. p. 40).

The frigate-birds, petrels, gannets, boobies, &c., that frequent in numbers the guano islands of the Pacific, will present opportunities of investigating this subject rarely found elsewhere. Not only the crops, but also the feathers and feet should be examined, since seeds have been sometimes found adhering to sea-birds that have been sitting on broken eggs. The industries connected with the ocean-ranging mutton-bird in Bass's Straits, and with the grebe in South America, may afford other opportunities. The seal-fisher in the Southern Ocean, and the sportsman on some remote coral islet, the voyager around the Cape, and the lighthouse-keeper in southern climes, these and many others might take a practical interest in this subject. It is important that not only should the seeds and fruits be preserved and sent to Kew, but that the species of bird should be known; and for this purpose, where there is any doubt, the wing or head of the bird might be also sent. H. B. GUPPY.

May 27.

Nose-Blackening as Preventive of Snow-Blindness.

As a partial answer to Prof. Ray Lankester's inquiry on nose-blackening as preventive of snow-blindness, may I offer some observations which I have made in my many wanderings in the higher Alps in early summer, when I have necessarily had much experience of the effects of snow on the human body?

But first I should like to draw attention to a letter of the Hon. Ralph Abercromby in NATURE (vol. xxxiii. p. 559), which he was kind enough to send me, relating some experiences on nose and face blackening in Morocco to prevent sand glare, in Fiji to prevent water glare, and in Sikkim to prevent snow glare. It was very curious that the Fijians, who ordinarily painted their faces white and red for ornament, would, before going fishing on the reefs in the full glare of the sun, blacken them. Mr. Abercromby draws attention very naturally to "the strange anomaly of physiological experience apparently contradicting the teachings of pure physics. Charcoal black, which is used in physical experiments as the best absorbent of every kind of heat radiation, is practically used by three races at least, to protect one of the most sensitive human organs from reflected light and heat."

Experience has, I think, sufficiently shown that snow-blindness and snow-burn, or sunburn on snow, own the same causes for their production; and, as nowadays both guides and climbers in the Alps invariably take the precaution of protecting their eyes with coloured spectacles, snow-blindness is rarely heard of. My observations are almost entirely confined to the causes of sunburn.

It will, I think, be readily conceded by Alpine climbers that sun on the snow burns more quickly than on rocks or in the heated valleys at a lower elevation. This increased power of burning appears somewhat singular when one reflects that the heat rays must be occupied in the melting of the snow, and thus rendered latent.

Iron-workers, glass-workers, and others are constantly exposed to a heat of 400° or 500° F., and yet do not become burnt; and there can be little doubt that the enormous radiation from heated rocks and valleys, in addition to the direct rays of the sun, make up an amount of heat far greater than is ever experienced on even a very sunny snow slope, and yet one does not become sunburnt. No doubt the surface of the snow reflects and disperses much heat, but certainly far less than it receives, as heat rays are absorbed and rendered latent by the snow-melting and evaporation. Experience fully corroborates this, for one may often lie on one's back and freely expose the face for long periods to the sun and yet remain unburnt. There must therefore be some other factor in sunburn than heat alone.

In discussing the subject with Prof. Tyndall, he added the very interesting and significant fact that he was never more burnt on snow than whilst experimenting with the electric light at the North Foreland Lighthouse, where there was no heat sufficient to produce such an effect.

I am aware that sometimes, in peculiar conditions of the atmosphere, the direct sun's rays will burn. I have met with some singular instances where several persons have been burnt on the same day, even in England, who had never previously suffered in that way. I am further aware that sometimes (not always) in a dead calm on a ship's deck one may be severely burnt, and that in boating on a river the same may occasionally happen. Masks and veils have been long used as a protection on snow, and are more or less successful; *brown* veils and glasses in my experience being the most efficient. As bearing upon this, I may mention that a friend of mine after an ascent on snow had an enormously swollen face, and I observed that in the general swelling there were many pits or depressions, and that each pit corresponded to a freckle: the irritating rays had been intercepted by the brown colour of the freckle. About the same time, I encountered a paragraph in the *Lancet*, saying that a German *savant* had been experimenting on the effects of sunlight on the retina, and had found that it had destroyed the visual purple of the retina, but that the action was modified by transmitting the sun's rays through various coloured glasses, and that when transmitted through *brown* glass the purple of the retina was unchanged. I have never seen any corroboration of these assertions, but they are worthy of further consideration. Stimulated by these observations, I painted my face brown with water-colour, and spent many hours on the snow of the Gorner Grat on the same day that about eighty out of a hundred people who were staying at the Riffel Alp went up to witness the first ascent of the season of Monte Rosa. In the evening everyone except myself and my daughter, who had carefully protected herself with a brown veil, was more or less severely sunburnt, whilst the remaining visitors, who had spent the day on the rocks and mountain-sides in the full sun, were untouched. Connected with this is the fact that visitors to the Engadine in winter become extremely brown, as though coloured by walnut-juice, whilst in summer, unless they go on the snow, this is not so, although of course the heat is greater. I have been there in winter and summer, and have had many opportunities of confirming this observation. Then again the very brown colour of the *châlets* is only to be seen at high altitudes where snow is, and even those parts of the *châlets* which by their position cannot receive rays reflected from snow do not become brown. And over the doors of these brown *châlets* in which the cows are kept the wood is invariably white and colourless just at that part which would always have, steaming up, the warm moist breath of the cows, and by this moisture the reflected rays would be intercepted. I think that all these observations bear upon and are related to the question raised by Prof. Ray Lankester.

I have made many other experiments and observations, but for brevity's sake I omit them, as I think I have said enough to show that the subject is a large one, and worthy of consideration. In a comment on Mr. Abercromby's letter abovementioned, Petrie says, "We should not look at the surface skin, which is constructed to bear local variations of temperature, &c., but at the delicate tissues beneath. White skin," he adds, "is translucent, but black stops out solar energy." It is possible that sunlight reflected from snow may have an influence in producing the improved health of consumptives who remain in the Engadine in winter, and Mr. Abercromby reminds me that the quality of heat which causes snow-burnt is not that which causes sun-stroke. Sun-stroke is very rare (if known at all) on mountains. Equatorial countries—Ceylon, Borneo, West Indies, &c.—are not the worst for sun-stroke; but sub-tropical and semi-tropical dry countries, such as Scinde, North-West Bengal, United States, Italy, &c.

He also says that photography is much slower in equatorial than in these latter countries. The cause undoubtedly is the absorption of violet and ultra-violet rays by water vapour, which is in excess near the Line. Photography is rapid—except for blue sky—at high altitudes. ROBERT L. BOWLES.

Folkestone, May 23.

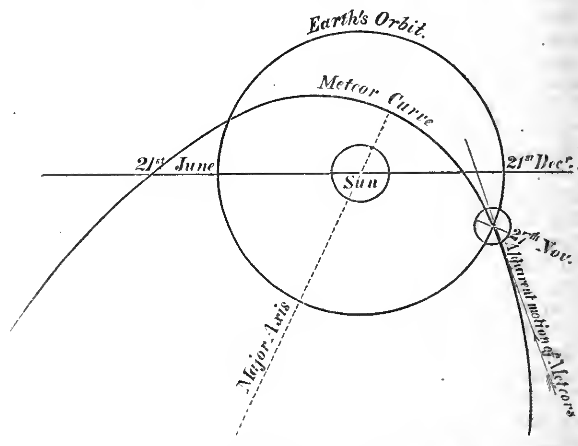
Mysterious Sky Lights.

ON turning over some back volumes of NATURE in search of information concerning the spectrum of the zodiacal light, I have discovered something which appears to be interesting and suggestive, viz. several communications describing what the writers supposed to be abnormal displays of the zodiacal light, displays occurring at the wrong time, *i.e.* near to the periods of the solstices instead of those of the equinoxes, and displays having the wrong shape, lacking the conical outline, but nevertheless nearly in the right place. The most interesting of these letters are from Mr. Maxwell Hall, and dated from Jamaica. He was so much exercised by the heterodoxy of the appearances he observed that he suggested a new theory, and illustrated it by a diagram on p. 204 of vol. vii.

He says in this letter that "for several nights lately the zodiacal light has been exceedingly bright and well-defined, and *more particularly on the nights of November* 24 *and* 27; on the evening of the 24th I found an explanation of what had often perplexed me before, viz. the existence of a faint, isolated band of light across the zenith, but as soon as it was dark in the evening, the zodiacal light was distinctly seen to *stretch across the whole sky*, forming that faint band of light previously observed; I then began to note its position, *but the best observations were made on the night of the 27th, when it was most distinct.*"

The italics in the above are mine. The dates given, November 24 and 27, 1872, are those of the remarkable meteoric shower supposed to be connected with the lost comet, Biela. The grandest display was on the 27th. May not the luminosity stretching "across the sky" have been due to sunlight reflected from the meteoric matter lying outside of the earth's atmosphere? Such a spurious zodiacal light does not demand our actual plunging into the meteoric stream producing it, but should be observable whenever such a stream exists between us and the sun, its apparent breadth varying with its actual breadth and its proximity to the earth.

On p. 85 of the same volume is a diagram of the Biela



meteor-path showing its relation to the earth's orbit and to the sun. From this, reprinted above, it is evident that the meteors should display a spurious zodiacal light at the time named, and on to that of the winter solstice, and later. In vol. xi. of NATURE, p. 115, reference is made to a letter from Mr. Hind, dated December 7, 1874, in which he points out "that the zodiacal light has been conspicuous for the last few evenings; and for several years past this phenomenon has been much more marked in December and January than about the vernal equinox."

The pages of NATURE and those of some of the older volumes of the *Gentleman's Magazine* contain many records of mysterious streaks and bands and "pillars" of light seen after sunset, variously ascribed to zodiacal light, to aurora borealis, celestial phosphorescence, &c. If I am right in assigning the spurious zodiacal light of the period above named to the Biela meteors, careful observations of such celestial luminosity in relation to other well-known meteor-streams may be very frui ful.

The Grange, Neasden. W. MATTIEU WILLIAMS.

Curious Apparent Motion of the Moon seen in Australia.

CAN any of your readers explain the phenomenon described in the following extract from a letter received from my daughter residing in Maryborough, Queensland, Australia:—

"We saw such a curious phenomenon on Sunday night, about 10.30. Miss C——, Miss H——, and I were sitting in the balcony, when we noticed the *moon apparently dancing up and down.* It is on the wane, so looked so extraordinary. The motion was visible only when she was behind a narrow stratum of cloud, and continued at intervals for thirty minutes. I felt quite seasick with watching it, and Miss H. was so frightened; she thought there might be an earthquake coming, so went to bed in her clothes to be ready for an emergency. Our house would soon fall in an earthquake, its walls are thin, and no cellars."

I presume the phenomenon is connected with the varying refrangibility of the atmosphere, perhaps arising from the mixing of hot and cold air; but should be glad of further information.

Park Corner, Blundellsands, May 27.

Another Specimen of *Lepidosiren paradoxa.*

IT may interest some of your readers to know that I have lately received another specimen of this rare fish from my friend Dr. J. Barbosa Rodriguez, the energetic Director of the Museu Botanico do Amazonas at Manáos. This is the *fifth* specimen known. A short notice of the fourth specimen, an adult female of large size, caught in the Igarapé do Aterro near Manáos, also presented to me by Dr. Barbosa Rodriguez, appeared in NATURE more than a year ago (vol. xxxv. p. 343). Dr. Rodriguez published a note on that specimen in the *Jornal do Commercio* of Rio de Janeiro for October 15, 1886. I state this as his note might easily be overlooked, not having appeared in a scientific periodical.

The last specimen received was caught at Autaz near the Madeira River in September 1887; it came, Dr. Rodriguez writes, from a mud-pool, whence it issued forth wriggling on the mud during rain-storms. My friend received it dead and in a state of incipient decomposition; he did all he could to insure its preservation, but when it reached me all I could save was the skeleton and portions of the skin and tougher muscles. These I have put in strong alcohol for future study. This specimen is considerably smaller than the one previously received, being, as far as I can judge, about 0m. 400 millim. in length.

At Autaz this fish is called *Trayra-boia*, or *Turum-boia*; the latter name is onomatopœic for *Turum*, which expresses the grunt made by the fish, and *boia* means "snake." On the Rio Mahu, an affluent of the Rio Branco, Dr. Rodriguez tells me that the name of this fish in the Makuchy dialect is *Aramó*.

Dreams.

MR. R. L. STEVENSON, in his "Chapter on Dreams" in *Scribner's Magazine* for January last, brings forward one difficult point that must have puzzled many dreamers besides himself. The point is that the dreamer is often in the position of an ignorant onlooker, who, only when the plot or story is complete, sees the drift and motive of the different incidents that have been enacted before his eyes by what Mr. Stevenson calls "the Little People who manage man's internal theatre."

Perhaps it is one step further on in the puzzle to have the interpretation only vouchsafed to one after awaking; and the following example may be of some interest.

Much of my dreaming goes on in the form of reading; and it once happened to me to awake while looking at the outside of a pamphlet I dreamt I was holding. I saw it vividly enough before me; it had a mud-coloured cover, and the title was printed on it in plain Roman capitals: "Food, or the astrology of every day." "But this is nonsense," I thought; until, still having a vivid view of the title before me, I observed that the rough brown paper had been rubbed up after the word "the," and that there was a wide gap between it and the "astrology." Evidently a letter was missing, and I at once conjectured that the word had been printed "gastrology." But this I did not arrive at till I was wide awake.

I come back to Mr. Stevenson's query, "Who are the Little People?" and how comes their amazing independence of their employers?

E. H.

Strange Rise of Wells in Rainless Season.

A HOUSE near Fareham, standing in its own grounds, is principally supplied with water by two wells, about 16 feet deep. They are usually quite full in winter, and gradually empty before autumn. Owing to the small amount of rain last winter, the beginning of March found the wells with only 3 feet and 2 feet of water respectively: when, after a continuance of north-east wind, *without rain*, but with half a gale blowing, the water in these wells rose 14 feet and 12 feet.

Can you or any of your readers explain this mystery? There is a tradition in the neighbourhood that it is customary with the wells in the district to rise with a heavy gale even without rain; and a similar phenomenon has been observed before by my informant.

May 23.

Milk *v.* Lightning.

IN Emin Pasha's letter published in NATURE (vol. xxxvii. p. 583), the Sudan Arabs are said to have a superstition that fire kindled by a flash of lightning cannot be extinguished until a small quantity of milk has been poured upon it. A similar belief seems to have existed formerly in this country. The earliest register-book of this parish contains the following note:—

"In the yeare of our Lord 1601 and uppon ye 14 day of May beinge thursday ther was great thundringe and lightninge and ye fyer descendinge from heaven kindled in a white-thorne bush growinge neere to a mudd-wall in Brook-street westward from Thomas Wake his house, it burned and consumed ye bush and tooke into ye wall about on yeard then by milke brought in tyme it was quenched and it did noe more hurt."

JOHN CYPRIAN RUST.

The Vicarage, Soham, Cambridgeshire, May 23.

The Renewed Irruption of *Syrrhaptes*.

MR. SCLATER having requested me to contribute to *The Ibis* an account of the present visitation of *Syrrhaptes* similar to that which I compiled for that journal in 1864, I would ask for information on the subject to be sent to me, and especially cuttings from foreign newspapers, the name of the publication and the date being always indicated thereon. I must add that I do trust my task will not be the unpleasant one of merely recording senseless slaughter. In 1863 the species bred both in Denmark and in Holland. There is no reason why it should not, if unmolested, breed this year in many parts of Britain. The visitations of 1872 and 1876 were of insignificant proportions, but that of the present year would seem to be of considerable magnitude, and sanguine hopes might be entertained as to the result if the malign influence of the "collector" could be neutralized or withstood.

ALFRED NEWTON.

Magdalene College, Cambridge, May 27.

"The Shell-Collector's Hand-book for the Field."

As your reviewer (NATURE, May 17, p. 51) has shown that the little book which bears the above title is certainly worth a large share of "powder and shot," I may, in all fairness, be allowed to reply to those strictures made by him which are the most unfair, and which I consider warrant a reply from me. In the first place, it is quite apparent that he has never used the "Authenticated British List" published by the Conchological Society, where he would have found *Clausilia parvula*, *C. solida*, and *Zonites draparnaldi* excluded, doubtless, on reliable authority; while *Bulimus Goodallii*, *Vertigo tumida*, and *Planorbis dilatatus* are included, also, doubtless, on reliable authority, as recognized members of the British fauna, even if they be "casuals." He has also, it is quite apparent, never read Prof. Macalister's "Introduction to Animal Morphology," where he will find it stated on p. 286 that "the operculum has always more conchiolin in its composition than the shell whose mouth it closes." He does not know, it is also quite apparent, that Pisidium and Sphærium are British fresh-water mussels, and *siphonated* British fresh-water mussels too, there being one siphon in the former and two in the latter genus (cp. the description of these genera in Westerlund's "Fauna of Sweden and Denmark"). He can scarcely know that the epiphragm has been called by some authors (as instance Macalister) the clausilium; and although recognizing this on p. 5 of my "Hand-book," I have described in a footnote to the genus Clausilium (p. 44) the only structure which we recognize to-day under that name. He does not know, it is evident, that Prof. Milnes Marshall ("Practical Zoology," p. 106) states that "the periostracum or outer layer is horny and uncalcified. To it the colour of the shell is due," and that "the middle layer" "is densely calcified, and has an opaque porcellanous appearance." And he scarcely knows that in Huxley and Martin's "Course of Elementary Instruction in Practical Biology," p. 274, the aperture of the shell is spoken of as the *peritreme* and not as the *peristome*, and that in the majority of works on comparative anatomy it is also solely mentioned under that name. I think it also my duty to tell your reviewer that the teeth-formulæ were not copied from Lankester, as he supposes, but from Woodward, and that upon comparison I find the copy correct (cp. Jeffrey Bell, "Comparative Anatomy and Physiology," p. 136).

In the second place, with regard to those other strictures which I can characterize by no other name than *mere whims*. It is a mere whim, for instance, to consider *Anodonta anatina* as a variety of *A. cygnea*, since such has never yet been generally recognized. It is a mere whim to believe that *Achatina acicula* should be *Cæciliancella acicula*; *Bulimus acutus* should be *Helix* (*Cochlicella*) *acuta*; *Zonites* should be *Hyalinia*," and I had rather remain with my old system of nomenclature than get so inextricably entangled in the medley of new systems made by Continental workers, all of which systems differ the one from the other as "chalk from cheese." It is a mere whim to imagine that chapters on "The Anatomy of a Snail" and "The Anatomy of a Fresh-water Mussel" should have been excluded since the basis of systematic zoology is anatomy. And it is a mere whim to cavil at the inclusion of the vars. *minor*, *maxima*, and "*albida*," (*exalbida*, if you please, Mr. Reviewer, for so was it named by Menke), and the monstrosity *sinistrorsum* of *Helix aspersa*, since Dr. Gwyn Jeffreys and Moquin-Tandon have named varieties and used variety-names, and since Prof. E. von Martens, than whom no better conchologist, expressly mentions that "it is certainly desirable that every local form, well-marked zoologically or geographically, should have a distinct name." And may I turn a reviewer on my own book, and ask myself how it is that I did not, as your reviewer desires, give the localities for every species, and make the book costly, and, by so doing, take it away from the reach of the poorer classes? Why also did I not give the definite localities for the now local species, when I considered rightly that some of them may turn up in other, and, perhaps, far distant spots to those now known? In conclusion, I would point out to your reviewer—for I must not occupy your valuable space to any greater extent—that as there is a virtue in the every-day affairs of this our mundane life which, to quote Seneca, is "the only immortal thing that belongs to mortality," so, as certainly, is there a virtue in right reviewing which is quite as exacting and quite as important to always bear in one's remembrance.

J. W. WILLIAMS.

51 Park Village East, N.W.

IN reviewing Dr. Williams's little book, I wished not merely to point out the author's mistakes, but to guard young conchologists, to whom the book is addressed, from placing too great reliance on the statements it contains.

I felt also convinced that the author was not practically conversant with his subject; indeed, that his knowledge was purely derivative, and this the foregoing letter fully confirms.

I will not occupy space with a detailed criticism on the author's method of compilation, but will simply refer to a single instance, quoted to show his want of care in referring to the original sources of information, so needful in such a task. The method of numeration of the tooth-formula, referred to by me as incorrect at p. 7 of the "Hand-book," is now justified by the author, who quotes Woodward as his authority; but upon referring to my brother's "Manual" I find that my statement was fully justified by the fact that the quotation is *not correct*, it having been taken by Dr. Williams from Prof. Jeffrey Bell's "Comparative Anatomy," where my brother's name is given as the authority for the instances quoted, and not for the whole paragraph to which it is appended, and which does not appear in his book. To the second part of Dr. Williams's *whimsical* letter I feel sure it is needless to reply.

HENRY WOODWARD.

129 Beaufort Street, S.W., May 28.

Freaks of Nature.

I INCLOSE a letter from my grandson Charles, a boy, son of St. Vincent Erskine, the explorer, with whose travels you are probably acquainted.

This singular instance of a change in the habits of birds, consequent on the advance of civilization, is extremely important and interesting, as it evinces almost reasoning powers and adaptation of habits to circumstances. As you are aware, some birds in South Africa build their nests on the pendant boughs of willow-trees as a defence against snakes and iguanas.

These willows, like other trees in Natal, are rapidly becoming scarcer, as they are cut down, whilst the boys who take the nests increase. This is, no doubt, the cause of the birds changing their nests to the telegraph-wires, where they are also safer from their natural enemies.

It would be interesting to know whether similar instances occur elsewhere.

D. ERSKINE.

47 Gratton Road, Kensington, May 25.

P.S.—It is remarkable also that the hole is at the side instead of the bottom, showing that the bird was aware that the situation was snake-proof. Darwin would have been glad of this proof of evolution.

WHILE watching the landscape of Natal between Ladysmith and Pietermaritzburg from a Natal Government Railway carriage, I saw some nests of the "golden weaver" bird. There were four of them hanging in a row, close together. They were the round kind, without the long arm. On one of the nests sat a cock weaver bird, but I saw no hens.

The nests seemed to be one or two years old, except one, which was greener than the others, and most certainly one of this season's. The chief peculiarity seemed to lie in the fact that the birds had woven grass round the wire for some six or eight inches, and two or three inches in circumference, before beginning to make the nest, and that the bird had to deal with a horizontal wire instead of a vertical stick or a branch. The bird always twists the grass round the branch (if he builds on a vertical twig) for some way up among the leaves and stalks, leaving the long ends free, thus forming his foundation. Weavers prefer to build on trees where the long slender twigs droop towards the ground, and so afford a nice vertical slender support. They are especially fond of the weeping-willow, whose slender switches generally branch off into two small shoots at the end: between these the bird loves to build his nest. Besides, the willow has lots of leaves very near together, and so holds the straws very well. On the wire he had no such support, but had to trust to his own ingenuity to overcome the novel situation, which task he seems to have accomplished very well.

The entrance to these nests was not at the bottom, as usual, but by a hole in the side, and all the nests did not look the same way.

I suppose there was only one nest a season or two ago, with a single pair of birds; soon we shall have a long string, or rather wire, of these ingeniously built homes with their happy quarrelsome occupants, making enough noise to stop all the messages ever sent that way. They will hear all the "Government" secrets: then we will be able to say truly, "A little bird told me."

C. H. ERSKINE.

WHIRLWINDS, WATERSPOUTS, STORMS, AND ROTATING SPHERES.[1]

IT is often necessary, in many branches of science, to halt in our steady progress along the beaten roads of induction, and say, "*Fiat experimentum.*" We may not always be able by this means to reproduce exactly all the physical conditions of the phenomenon, we are investigating, or to evolve a test crucial enough to enable us to decide between rival hypotheses. Nevertheless, the power we thus gain, especially in the case of an atmospheric phenomenon, of seeing the entire system of action in a *coup d'œil*, of gauging its relative proportions, and of examining its dependence and effects on its *entourage*, can hardly be over-rated.

Such would appear to have been M. Weyher's object in the delicate and ingenious experiments which he has so skilfully elaborated and described in the pamphlet of 91 pages before us.

The physical theory of atmospheric eddies, including the rotating flat disk or cyclone, and the rotating column which manifests itself as a tornado, waterspout, or dust-whirl, according to variations in its intensity and surrounding circumstances, has lately been developed to an extent not generally known, principally by Ferrel, Sprung, Oberbeck, and Marchi. It is therefore decidedly satisfactory to those who believe in the progress of meteorology by rational theory and deduction, to find that the motions exhibited in M. Weyher's experiments, in which the conditions in Nature are very fairly imitated, agree in every point with those which have been deduced from their physical theory.

Theory, for example, shows that a tornado is due primarily to an unstable condition of saturated air, accompanied by a gyrating motion (which may initially be very small, and which is practically always present to

[1] "Sur les Tourbillons, Trombes, Tempêtes, et Sphères Tournantes: Étude et Expériences." Par C. L. Weyher. (Paris, 1887.)

some extent, owing to the earth's rotation), relative to some central point.[1]

Given these conditions, the rest follow as necessary consequences, viz. (1) a current ascending up the *axis*, combined with rapid rotation round it; (2) a hyperboloidal funnel of rarefied air tapering downwards, and reaching the earth when the action is powerful, round the sides of which a condensed vapour-, or so-called water-spout, should usually prevail, owing to the sudden rarefaction of the air entering the central area through the sides or at the base, with the consequent lowering of the plane of condensation from the cloud-level which it usually occupies. When, therefore, it is said that "a waterspout is simply the cloud brought down to the earth by the rapid gyratory motion of the tornado,"[2] it is not meant that the cloud is actually carried downwards by an aërial current, since by theory the motion is precisely in the opposite direction; but that the *conditions* of *condensation* are propagated downwards from the cloud-stratum where they first commence. Neglect of this consideration, as well as the physical fact that condensation can only occur under most exceptional circumstances in a *downward* current, has led to many false deductions from apparent circumstances.

Theory, moreover, indicates that the current up the axis, together with gyration round it, which, by the conservation of rotational momentum, may become exceedingly rapid as the air approaches it, must combine to give a spiral character to the movement near the axis, while the conditions of continuity equally demand that there should be a compensatory descending current somewhere in the vicinity, gyrating spirally in the same sense, and of only moderate velocity, owing to its greater distance from the axis.

At the base of a tornado, or its milder form of waterspout, there should also be a rising up of the water at sea, or of light objects on land, which are supported by the ascending current until their collision or size carries them outside the central area, when they fall back to the earth, or to points where they are again brought within the influence of the whirl-currents. These and many other

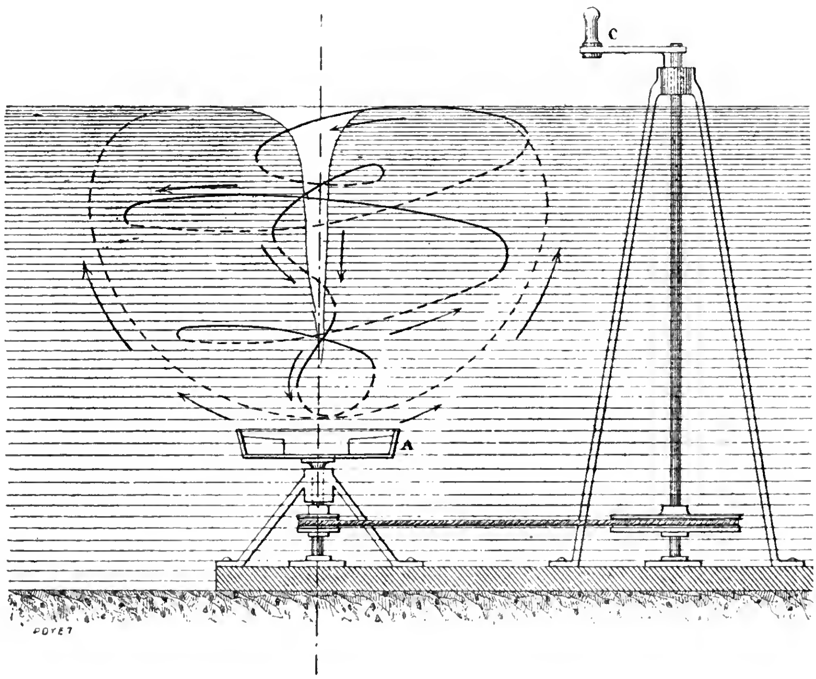

FIG. 1.

minor characteristics of tornadic action are confirmed and illustrated by M. Weyher's experiments.

M. Weyher commences by examining the conditions which prevail in an eddy produced in water, either by an outflow through a sluice, or a momentary rotation imparted by the stroke of an oar. In the former case the motion is well known, but in the latter it is somewhat new to find that besides the rotation round a vertical axis there is an interchanging vertical motion such that each particle describes a descending helix down the axis of the whirl, and ascends in a helix of the same sense to regain the surface.

Fig. 1 shows the same circulation produced by the revolution of a tourniquet, A.

If this figure be looked at upside down, it substantially depicts what is believed to be the motion of the air in a whirlwind, waterspout, or tornado, and is precisely similar to what is found to be the motion round those artificially produced by M. Weyher.

The important point to notice with respect to the water eddies, which are introduced mainly to show their analogy to air-whirls, is that, according to M. Weyher, their source of action must be at some distance *below* the surface. By artificially causing the liquid to rotate at its surface only, he found it impossible to obtain the central descending funnel of a complete water eddy.

A similar condition is found to hold in an *inverse* sense in the case of artificially-produced air-whirls. The action must in their case originate in the *upper* part of the air-column, whence the motion is communicated by degrees to its lower boundary. The analogy, therefore, between the water eddy with a descending motion round its axis and the atmospheric whirlwind is completely *inverse*, and not *direct*, as some have supposed.

[1] Sergeant Finley found, in his review of 600 tornadoes in the United States, that the direction of rotation round the axis was invariably cyclonic, or against watch-hands ("Signal Service Notes," No. xii. p. 10).

[2] "Recent Advances in Meteorology" (p. 301), by W. Ferrel. (Washington, 1885.

M. Weyher next proceeds to discuss the motions which should theoretically occur in an air-whirl. These are shown in vertical section in Fig. 2.

In the annular region bordering the inner rarefied space, and represented by A *a c* C, *b* B D *d*, the air is assumed to be rendered denser than the normal by the centrifugal force of gyration, and according to M. Weyher it is by the *descent* of this denser air upon the depression caused by the air below rushing up to fill the central area, that the rotation system propagates itself from above towards the earth.

We do not think this explanation is either correct or necessary. It is contrary to the physical theory that there should be a sheath of dense air surrounding the rarefied region, and, apart from this, friction, and the transference of air up the axis from its lower end amply account for the downward propagation.

The most interesting of M. Weyher's experiments are those in which he artificially produces the phenomena of the waterspout. By means of a rotating tourniquet placed over cold water, an aërial eddy is caused which draws up the water, in the form of a spout composed of drops, to a considerable height; but when the water is heated, a clearly-defined condensed-vapour-, or, as it is popularly

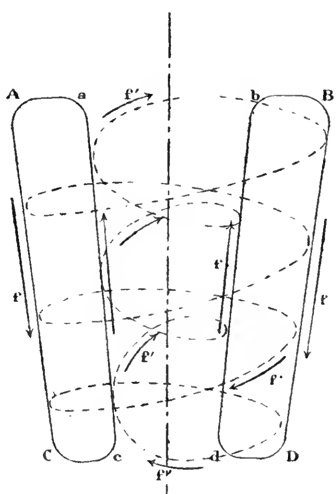

FIG. 2.

termed, water-spout, makes its appearance, like that shown in Fig. 3, which represents a form of the apparatus suitable for a chamber experiment.[1]

With from 1500 to 2000 rotations per minute, the vapour from the heated water is found to condense itself into a visible sheath enveloping a clearly-defined and rarefied central nucleus, conical, and tapering downwards. The diameter of the sheath is from $\frac{3}{4}$ inch to 1 inch. Besides this vapour-spout, water-drops are carried up, as in natural marine spouts, until they are thrown out beyond the influence of the upward current.

Other features of spouts are then imitated, particularly what is called the *hérisson*, which appears to be identical with what the French sailors call the *buisson*, or bush-like ploughing up of the sea, which occurs at their bases, both before and during the period of complete formation. This is effected by placing twenty or thirty small air-balloons in the place of the water, underneath the tourniquet. These are then seen to rise up a short distance, and fall back in graceful interlacing elliptical curves. The entire motion throughout the *hérisson*, as well as the whole system, is further studied by placing underneath the tourniquet a quantity of oatmeal in a glass vessel, and observing its motion by means of eye-pieces fitted into the top of the vessel. The motions are thus seen to be precisely the same as those theoretically inferred, and when the rotation is stopped, the ascending spires of the currents at the lower end, are found engraven in lines on the finer particles, which, in obedience to these currents, lie in a conical heap round the vertical axis of the whirl.

Several other experiments are made with cotton-wool and smoke, each of which exhibits some special feature characterizing the spouts of Nature.

The pressure and temperature conditions in different parts of the area are next investigated.

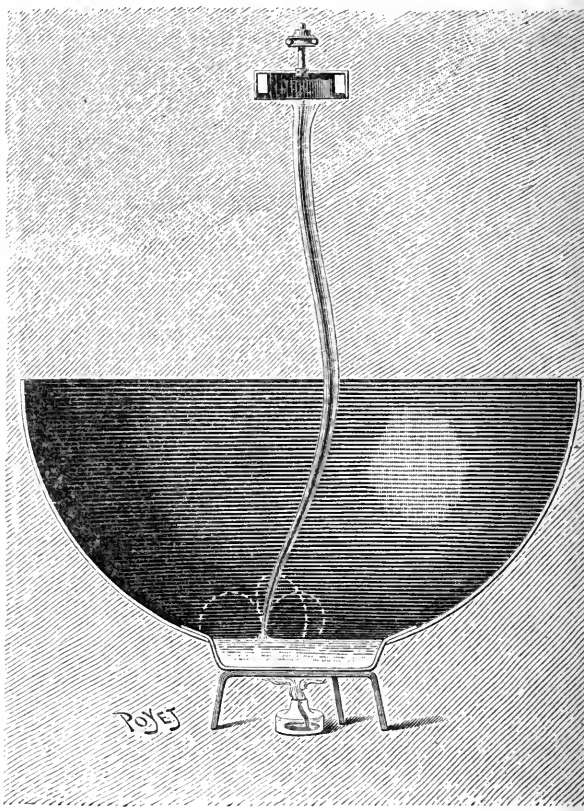

FIG. 3.

By means of a manometer, it is found that the rarefaction at the centre of the rotating tourniquet is transmitted almost unaltered in intensity (probably proportionally diminished in area) to the centre of the whirl on the surface, while the thermometer at the same point, at first shows a fall and then a rise of temperature, the latter evidently due to the friction of the rapidly moving air against the surface.

The analogous phenomenon of a cyclone is very fairly imitated by the apparatus shown in the accompanying diagram (Fig. 4), consisting of a large tourniquet placed over a table covered with a number of pins mounted with movable threads of red wool. The tourniquet is arranged so as to be capable of translation as well as rotation. At the centre, the table is pierced with a small hole at D, communicating by means of a caoutchouc tube with a manometer, which thus registers the changes of pressure

[1] For those desiring to repeat the experiment the dimensions are as follows. The tourniquet is made of tin from 5 to 6 inches in diameter by 1 to $1\frac{1}{2}$ inch in height. There are from 10 to 12 rectangular fans 1 inch by $\frac{3}{4}$ inch. The vessel holding the water is placed 31 to 39 inches from the tourniquet, and is from 7 inches to 1 foot in diameter by $1\frac{1}{2}$ to 2 inches deep. The hemispherical continuation of the vessel, to keep off local air-currents, which disturb the continuity of the spout, is 3 feet in diameter.

as the supposed cyclone passes over it. On rotating the tourniquet and passing it along over the table, the directions and positions of the threads are seen to indicate not only the horizontal, but also the vertical components of the winds thus produced, including the region of calm in the centre, as well as the downward and outward motion at the anticyclonic border. The variations of pressure recorded by the manometer, when plotted out, show a curve similar to that in a symmetrical cyclone, including the rise of pressure at the border where the motion is descending and outwards.

Hail is then explained, as being caused by vapour drawn up into the *hérisson* of what M. Faye terms a *trombe internubaire*, which descends from the upper regions as far as the surface of the cloud, whence the hail proceeds. The rest of the explanation, which mainly involves a continual churning up and down of the frozen particles, is similar to that given by Ferrel and Möller, except that the hailstones impinging upon one another at the focus of the *hérisson* are supposed, by the heat thus engendered, to aid in effecting the temporary melting of their surfaces necessary to account for the concentric coats of snow and ice they usually exhibit.

M. Weyher's experiments do not, of course, fulfil all the conditions which prevail in Nature, since in that case the rotation is doubtless kept up, after it has once been started in the air at some distance above the surface, by the upward movement along the axis, and the consequent aspiration of the surrounding air into the area of gyration. With this exception, however, there seems little wanting.

The position of the source from which the vapour is drawn is not so important as might be thought, since the vapour condensed in the natural waterspout is not the cloud actually brought down to the surface, any more than it is—except for the space of a few feet at its lower extremity—the water bodily carried up, but is the result of the condensation, by rarefaction, of vapour previously contained invisibly, but certainly amply enough for the purpose, right down to the earth's surface. In fact, the origin of the vapour, being at the base, more nearly imitates Nature than if it were only supplied above in the form of a cloud.

M. Weyher's experiments so far, therefore, bear out the hypothesis that a system of rotating air-currents above the earth's surface, causes tornadic, waterspout, and dust-spout phenomena, by an aspiration *towards*, and a flow *up*, its axis, and show that such a system can propagate itself and its accompanying effects downwards without assuming any downward component along the axis.

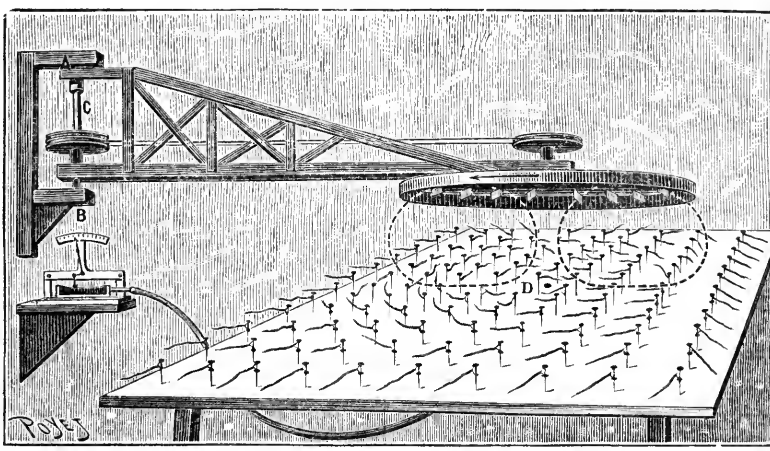

FIG. 4.

The last part of the work is devoted to a description of certain curious effects produced by rotating spherical tourniquets. Fig. 5 shows a convenient form of the apparatus, in which S represents a sphere made of eight or ten circular fans, fixed on an axis passing through two vertical disks whose function it is to keep off disturbing currents, and also to concentrate the action. M is an air-balloon, which, when the tourniquet is set in motion, is found to revolve round it in the plane of its equator, and be attracted instead of repelled.

M. Weyher thus explains this, at first sight, paradoxical motion. A rotating spherical ventilator draws in the air chiefly at its poles, and expels it in the plane of the equator, but, except *in this plane*, there is a general motion of the air all round *towards* the ventilator. The stream of air issuing from the ventilator in the plane of the equator is divided by the balloon, and forms vortices, which, together with the currents centrally directed on its reverse side, tend to urge it towards the ventilator. Whether this explanation be considered satisfactory or not, the balloon certainly revolves like a satellite round the ventilator. By means of floating gold-leaves, the action of the ventilator is seen to cause two dissymmetrical aërial whirls, whose inner gyrations commencing at some distance from the generating sphere, run round the polar axis in opposite directions, and meet on the plane of the equator. From thence the air jointly brought by these inner helices is driven outwards, and returns by similar helices, like the downward return-current of the tornado, to the points at the extremities of the prolonged polar axis. So far well, but we cannot quite admit the validity of the manometer experiment by which, on p. 74, the author attempts to show the existence of the aspiration in the plane of the equator requisite to explain the attraction it exerts on the air-balloon. The effect of velocity in decreasing pressure, as exemplified by Hawksbee's famous experiment, would probably mask any other vortical effects such as those sought by M. Weyher.

It appears to be a recognized custom for an author, after describing his experiments, to indulge in some pet speculations, and even to make the orthodoxy of the former an excuse for the frequently Utopian character of the latter.

M. Weyher certainly treats himself to an ample dessert of this description in his concluding section, in which, assuming the existence of a *ponderable* ether, the phenomena of the *tourbillon* are by analogy transferred to the solar system, which is supposed to be the *hérisson* of a whirl system reaching it from space, the sun being in the focus, and in which the planets, by the mutual influence of the ethereal whirls due to their axial rotation, cause simultaneously spots on the sun and cyclones on the earth.

We fail to follow M. Weyher here, and think it would have been better if he had not only hesitated, as he admits he did, but decided not to publish such wild speculations. His experiments are exceedingly instructive

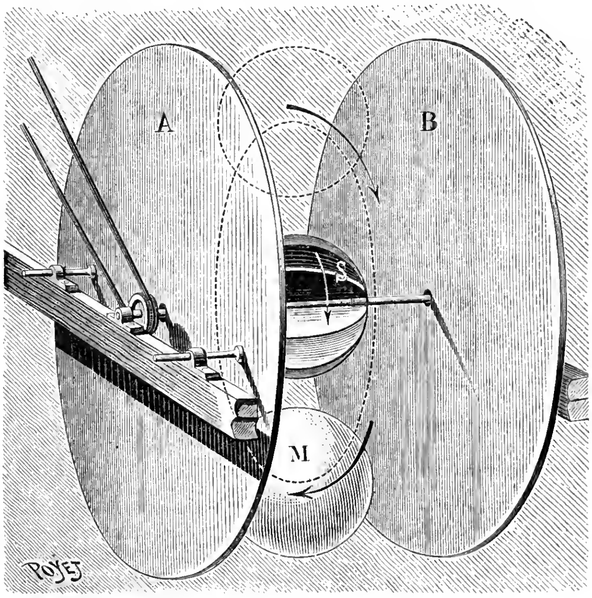

Fig. 5.

and suggestive, and if he can ultimately succeed in imitating the conditions of Nature more closely, we shall doubtless have an end of the theoretical polemics which have hitherto retarded rather than aided the progress of our knowledge of aërial motions and their causes.

E. Douglas Archibald.

TIMBER, AND SOME OF ITS DISEASES.[1]

VII.

If we pass through a forest of oaks, beeches, pines, and other trees, it requires but a glance to see that various natural processes are at work to reduce the number of branches as the trees become older. Every tree bears more buds than develop into twigs and branches, for not only do some of the buds at a very early date divert the food-supplies from others, and thus starve them off, but they are also exposed to the attacks of insects, squirrels, &c., and to dangers arising from inclement weather, and from being struck by falling trees and branches, &c., and many are thus destroyed. Such causes alone will account in part for the irregularity of a tree, especially of a Conifer, in which the buds may be developed so regularly that if all came to maturity the tree would be symmetrical. But that this is not the whole of the case, can be easily seen, and is of course well known to every gardener and forester.

If we remove a small branch of several years' growth from an oak, for instance, it will be noticed that on the twigs last formed there is a bud at the axil of every leaf; but on examining the parts developed two or three years previously it is easy to convince ourselves of the existence of certain small scars, above the nearly obliterated leaf-scars, and to see that if a small twig projected from each of these scars the symmetry of the branching might be completed. Now it is certain that buds or twigs were formed at these places, and we know from careful observations that they have been naturally thrown off by a process analogous to the shedding of the leaves; in other words, the oak sheds some of its young branches naturally every year. And many other trees do the same; for instance, the black poplar, the Scotch pine, *Dammara*, &c.; in some trees, indeed, and notably in the so-called swamp cypress (*Taxodium distichum*) of North America, the habit is so pronounced that it sheds most of its young branches every year.

But apart from these less obvious causes for the suppression of branches, we notice in the forest that the majority of the trees have lost their lower branches at a much later date, and that in many cases the remains of the proximal parts of the dead branches are sticking out from the trunk like unsightly wooden horns. Some of these branches may have been broken off by the fall of neighbouring trees or large limbs; others may have been broken by the weight of snow accumulating during the winter; others, again, may have been broken by hand, or by heavy wind; and yet others have died off, in the first place because the over-bearing shade of the surrounding trees cut off the access of light to their leaves, and secondly because the flow of nutritive materials to them ceased, being diverted into more profitable channels by the flourishing, growing parts of the crown of leaves exposed to sunlight and air above.

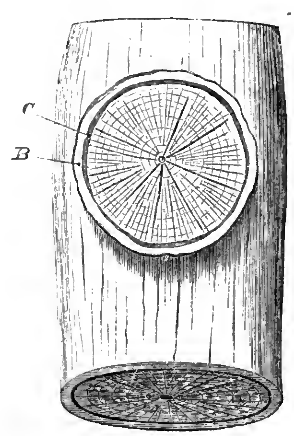

Fig. 21.—Portion of a tree from which a branch has been cut off close to the stem. *C*, the cambium of the branch; *B*, the cortex.

The point I wish to insist upon here is that in these cases of branch-breaking, however brought about, open wounds are left exposed to all the vicissitudes of the forest atmosphere; if we compare the remnant of such a broken branch and the scar left after the natural shedding of a branch or leaf, the latter will be found covered with an impervious layer of cork, a tissue which keeps out damp, fungus-spores, &c., effectually.

It is, in fact—as a matter of observation and experiment—these open wounds which expose the standing timber to so many dangers from the attacks of parasitic fungi; and it will be instructive to look a little more closely into the matter as bearing on the question of the removal of large branches from trees.

If a fairly large branch of a tree, such as the oak, is cut off close to the trunk, a surface of wood is exposed, surrounded by a thin ring of cambium and bark (as in Figs. 21 and 22). We have already seen what the functions of the cambium are, and it will be observed that the cut edge of the cambium (*C*) is suddenly placed under different conditions from the usual ones; the chief change, and the only one we need notice at present, is that the cambium in the neighbourhood of the cut surface is released

[1] Continued from vol. xxxvii. p. 516.

from the compressing influence of the cortex and bark, and owing to this release of pressure it begins to grow out at the edges into a cushion or "callus," as shown in Figs. 23 and 24. A very similar "callus" is formed in the operation of multiplying plants by "cuttings," so well

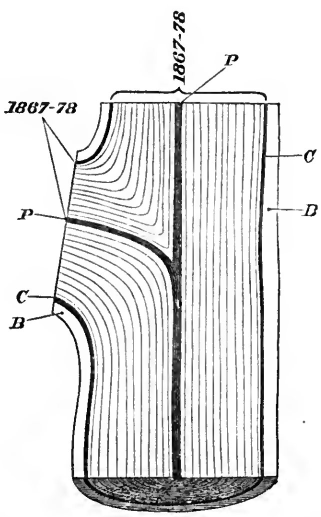

FIG. 22.—The same in longitudinal section. *P*, the pith of stem and branch; on either side of this are the twelve annual zones of wood produced during the years 1867–78, as marked. The cambium, *C*, separates these from the cortex, *B*.

known to all: the cambium at the cut surface of the "slip" or "cutting," is released from the pressure of the cortex, and begins to grow out more rapidly in the directions of less pressure, and forms the callus.

Now this callus (Fig. 23, *Cal*) is in all cases something more

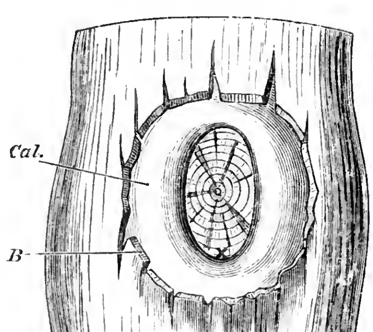

FIG. 23.—The same piece of stem four years later. The cushion-like development, *Cal*, resulting from the overgrowth of the cambium and cortical tissues of the cut branch, has extended some distance from the edges, and is covering in the exposed wood. *B* is the dead outer corky tissue, incapable of growth, and partially cracked under the pressures exerted by the thickening of the stem. The latter is somewhat swollen transversely, owing to the release of pressure in this region enabling the cambium to develop a little more actively here; the quicker growth of the occluding cushion in the horizontal direction is due to the same cause.

than mere cambium—or rather, as the cambium extends by cell-divisions from the cut edge of the wound, its outer parts develop into cortex, and its inner parts into wood, as in the normal case. The consequence is that we have in the callus, slowly creeping out from the margins of the wound, new layers of wood and cortex with cambium between them (Fig. 24); and it will be noticed that each year the layer of wood extends a little further over the surface of the wound, and towards the centre of the cut branch; and in course of time, provided the wound is not too large, and the tree is full of vigour, the margins of the callus will meet near the middle, and what was the exposed cut surface of the branch will be buried beneath layers of wood and cortex, between which lies the cambium, now once more continuous over the whole trunk of the tree (Figs. 25 and 26).

It is not here to the purpose to enter into the very interesting histological questions connected with this callus-formation, or with the mechanical relations of the various parts one to another. It is sufficient for our present object to point out that this process of covering up, or *occlusion*, as I propose to term it, requires some time for its completion. For the sake of illustration, I have numbered the various phases in the diagram, with the years during which the annual rings have been formed; and it

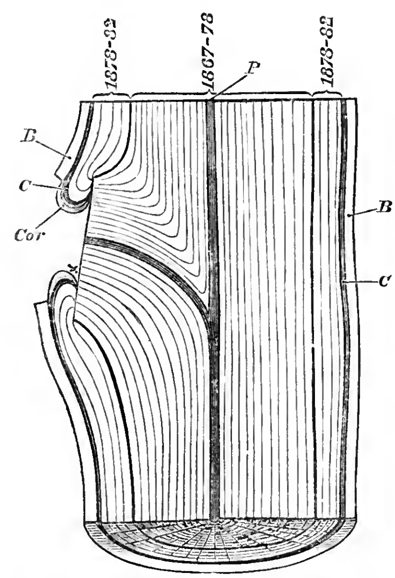

FIG. 24.—The same in longitudinal section: *P*, *B*, and *C* as before. The four new layers of wood formed during 1879–82 are artificially separated from the preceding by a stronger line. On the left side of the figure it will be noticed that the cambium (and therefore the wood developed from it) projected a little further over the cut end of the branch each year, carrying the cortical layers (*Cor*) with it. At ×, in both figures, there is necessarily a depression in which rain-water, &c., is apt to lodge, and this is a particularly dangerous place, since fungus-spores may here settle and develop.

will be seen at a glance that, in the case selected, it required seven years to cover up the surface of the cut branch (cf. Figs. 21–26). During these seven years more or less of the cut surface was exposed (Fig. 24) to all the exigencies of the forest, and it will easily be understood that abundant opportunities were thus afforded for the spores of fungi to fall on the naked wood, and for moisture to condense and penetrate into the interior; moreover, in the ledge formed at × in Figs. 23 and 24, by the lower part of the callus, as it slowly creeps up, there will always be water in wet weather; and a sodden condition of the wood at this part is insured. All this is, of course, peculiarly adapted for the germination of spores; and, since the water will soak out nutritive materials, nothing could be more favourable for the growth and development of the mycelium of a fungus. These circumstances, favourable as they are for the fungi, are usually rendered even more so in practice, because the sawyers often allow such a branch to fall, and tear and crush the cambium and cortex at the lower edge of the wound. These and other details must be passed over, however, and our attention be confined to the fact that here are ample chances for the spores of parasitic and other fungi to fall on a surface admirably suited for their development.

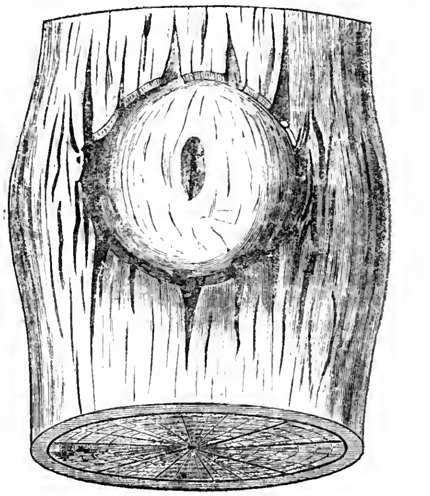

FIG. 25.—The same piece of stem six years later still: the surface of the cut branch has now been covered in for some time, and only a boss-like projection marks where the previous cut surface was. This projection is protected by cork layers, like ordinary outer cortex, the old outer cortex cracking more and more as the stem expands.

The further fact must be insisted upon that numerous fungus-spores do fall and develop upon these wounds, and that by the time the exposed surface is covered in (as in Fig. 25) the timber is frequently already rotten, usually for

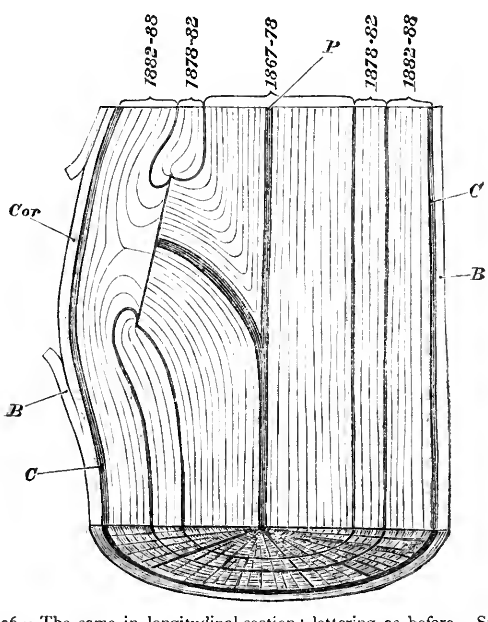

FIG. 26.—The same in longitudinal section: lettering as before. Six new layers of wood have been developed, and the cut end of the branch was completely occluded before the last three were formed—*i.e.* at the end of 1885. After that the cambium became once more continuous round the whole stem, and, beyond a slight protuberance over the occluded wound and the ragged edges of the dead corky outer layers, *B*, there are no signs of a breach.

some distance down. In the event of fungi, such as have been described above—parasites and wound-parasites—gaining a hold on such wounds, the ravages of the mycelium will continue after the occlusion is complete, and I have seen scores of trees, apparently sound and whole, the interior of which is a mere mass of rottenness: when a heavy gale at length blows them down, such trees are found to be mere hollow shells, the ravages of the mycelium having extended from the point of entry into every part of the older timber.

In a state of nature the processes above referred to do not go on so smoothly and easily as just described, and it will be profitable to glance at such a case as the following.

A fairly strong branch dies off, from any cause whatever—*e.g.* from being overshadowed by other trees. All its tissues dry up, and its cortex, &c., are rapidly destroyed by saprophytic fungi, and in a short time we find only a hard, dry, branched stick projecting from the tree. At the extreme base, where it joins the tree, the tissues do not at once perish, but for a length of from half an inch to an inch or so the base is still nourished by the trunk. After a time, the wind, or a falling branch, or the weight of accumulated snow, &c., breaks off the dead branch, leaving the projecting basal portion: if the branch broke off quite close to the stem, the wound

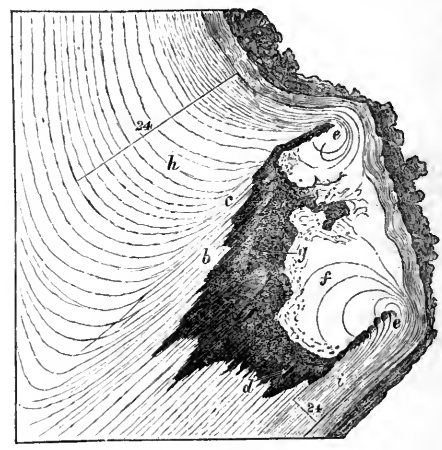

FIG. 27.—Base of a strong branch which had perished naturally twenty-four years previously to the stage figured. The branch decayed, and the base was gradually occluded by the thickening layers of the stem: the fall of the rotting branch did not occur till six years ago, however, as can be determined from the layers at *e* and *f*, which then began to turn inwards over the stump. Meanwhile, the base had become hollow and full of rotten wood, *g*. It is interesting to note how slight the growth is on the lower side of the branch base, *i*, as compared with that at *h* above: the line numbered 24 refers to the annual zones in each case. As seen at *b* and *d*, the rotting of the wood passes backwards, and may invade the previously healthy wood for some distance. (After Hartig.)

would, or at least might, soon be occluded; but, as it is, the projecting piece not only takes longer to close in, but it tends to rot very badly (Fig. 27), and at the best forms a bad "knot" or hole in the timber when sawn up. Of course what has already been stated of cut branches applies here: the wounds are always sources of danger so long as they are exposed.

It is beyond the scope of these articles to set forth the *pros* and *cons* as to the advisability of adopting any proposed treatment on a large scale: the simple question of cost will always have to be decided by those concerned. But whether it is practicable or not on a large scale, there is no question as to the desirability of adopting some such treatment as the following to preserve valuable trees and timber from the ravages of these wound-parasites. Branches which break off should be cut close down to the stem, if possible in winter, and the clean cut made so that no tearing or crushing of the cambium and cortex occur; the surface should then be painted with a thorough coating of tar, and the wound left to be occluded. If the cutting is accomplished in spring or summer, trouble will be caused by the tar not sticking to the damp surface. Although this is not an absolute safeguard against the attacks of fungi—simply because the germinal tubes from spores can find their way through small cracks at the margin of the wound, &c.—still it reduces the danger to a minimum, and it is certain that valuable old trees have been preserved in this way.

Before passing to treat of the chief diseases known to start from such wounds as the above, it should be remarked that it is not inevitable that the exposed surface becomes attacked by fungi capable of entering the timber. It happens not unfrequently that a good closure is effected over the cut base of a small branch in a few years, and that the timber of the base is sound everywhere but at the surface: this happy result may sometimes be attained in pines and other Conifers, for instance, by the exudation of resin or its infiltration into the wood; but in rarer cases it occurs even in non-resinous trees, and recent investigations go to show that the wood formed in these healing processes possesses the properties of true heart-wood. At the same time there is always danger, as stated, and we will now proceed to give a brief account of the chief classes of diseases to which such wounds render the tree liable.

The first and most common action is the decay which sets in on the exposure of the wood surface to the alternate wetting and drying in contact with the atmosphere: it is known that wood oxidizes under such circumstances, and we may be sure that wounds are no exception to this rule. The surface of the wood gradually turns brown, and the structure of the timber is destroyed as the process extends.

The difficulty always arises in Nature, however, that mould-fungi and bacteria of various kinds soon co-operate in and hurry these processes, and it is impossible to say how much of the decay is due to merely physical and chemical actions, and how much to the fermentative action of these organisms. We ought not to shut our eyes to this rich field for investigation, although for the present purpose it suffices to recognize that the combined action of the wet, the oxygen of the air, and the fermenting action of the moulds and bacteria, &c., soon converts the outer parts of the wood into a mixture of acid substances resembling the humus of black leaf-mould.

Now as the rain soaks into this, it dissolves and carries down into the wood below certain bodies which are poisonous in their action on the living parts of the timber, and a great deal of damage may be caused by this means alone. But this is not all: as soon as the decaying surface of the wound provides these mixtures of decomposed organic matter, it becomes a suitable soil for the development of fungi which are not parasitic—*i.e.* which cannot live on and in the normal and living parts of the tree—but which can and do thrive on partially decomposed wood. The spores of such fungi are particularly abundant, and most of the holes found in trees are due to their action. They follow up the poisonous action of the juices referred to above, living on the dead tissues; and it will be intelligible that the drainage from their action aids the poisonous action as it soaks into the trunk. It is quite a common event to see a short stump, projecting from the trunk of a beech, for instance, the edges of the stump neatly rounded over by the action of a callus which was unable to close up in the middle, and to find that the hollow extends from the stump into the heart of the trunk for several feet or even yards. The hollow is lined by the decayed humus-like remains of the timber, caused by the action of such saprophytes as I have referred to. Similar phenomena occur in wounded or broken roots, and need not be described at length after what has been stated.

But, in addition to such decay as this, it is found that if the spores of true wound-parasites alight on the damp surface of the cut or broken branch, their mycelium can extend comparatively rapidly into the still healthy and living tissues, bringing about the destructive influences described in Articles III. and IV., and then it matters not whether the wound closes over quickly or slowly—the tree is doomed.

H. MARSHALL WARD.

(*To be continued.*)

HERVÉ MANGON.

IN the current number of *La Nature* there is an interesting article, by M. Gaston Tissandier, on Charles François Hervé Mangon, whose death we announced last week. The following are the essential facts noted by M. Tissandier.

Hervé Mangon was born in Paris on July 31, 1821, and was trained by his father, a military surgeon, who devoted himself almost entirely to the education of his son. At the age of nineteen the young man entered l'École Polytechnique, and two years later l'École des Ponts et Chaussées. He afterwards acted as engineer for several railways, but his chief interest at that time was in science as applied to agriculture.

In 1850 he published his "Études sur les Irrigations de la Campine Belge," and on the "Travaux Analogues de la Sologne." This work attracted great attention, and brought about important improvements in the French laws relating to agriculture. Drainage was then scarcely known, even by name, in France. In 1851, M. Hervé Mangon published a work on the subject, which was considered so valuable that he received from the Academy of Sciences the decennial prize for the most useful work on agriculture issued during the previous ten years. His practical instructions on drainage, of a little later date, were widely circulated, and it is estimated that the results of his researches have led to an increase, in the French revenue, of fourteen millions of francs yearly. Irrigation, manures, chemical refuse, and everything by which land might be fertilized, were made by him subjects of prolonged and careful study. He visited the principal agricultural works and irrigations in France, Belgium, Scotland, Spain, and Algiers, and summed the knowledge thus acquired in his "Traité de Génie Rural."

These researches were followed by meteorological studies, in which he took the deepest interest. He invented or improved many meteorological instruments, and on his estate at Brécourt in Normandy he organized a model meteorological station, provided with the latest scientific improvements. Towards the end of his career he played a most important part in the reorganization of the French meteorological service, and he became the President of the Meteorological Council. He contributed also to the organization of the scientific mission to Cape Horn, and to many other enterprises useful to science.

As a Professor, he created at the École des Ponts et Chaussées the course on "Hydraulique Agricole" (1849); at the Conservatoire des Arts et Métiers the course on "Travaux Agricoles et de Génie Rural" (1864); and at the new Institut National the course on "Génie Rural" (1876), a science of which he may be considered one of the founders. He lectured with ease, and his expositions were always clear and methodical.

He possessed an extraordinary power of work. He rose early, carried on his own correspondence, and did all his literary work without assistance. His personal tastes were simple, and the activity of his body seemed to keep pace with that of his mind. He welcomed fellow-workers cordially, and readily offered them counsel and help, his disposition being one of rare generosity. He was skilful in working in wood and metal, and always kept in his library a quantity of apparatus made by himself. With this he was constantly experimenting, sometimes even getting up during the night to carry on some research of special interest.

In 1872 he was elected a member of the Academy of Sciences; in 1880, Director of the Conservatoire des Arts et Métiers; and in 1887, Vice-President of the Academy of Sciences. Notwithstanding the manifold calls on his time, he worked hard to secure the success of the Exhibition of 1867, and of all the succeeding Paris Exhibitions.

Believing it to be important that men of science should take part in politics, he entered the Chamber as Deputy for La Manche, and became Minister of Agriculture in the Brisson Ministry, in which he was of eminent service.

During the war of 1870 he gave proof of ardent patriotism. Night and day, during the siege of Paris, he made incessant observations in order to facilitate the despatch of letters by balloon. For six months he did not miss the departure of one of the balloons; he was always present, encouraging the aëronauts, and giving them valuable directions. When M. Tissandier was about to leave Paris in a balloon, laden with messages for the Government at Tours, M. Hervé Mangon said to him, "Vous avez bon vent est-nord-est; vous allez filer dans la direction de Dreux," and the balloon descended at the gates of that very town.

M. Hervé Mangon was the son-in-law of J. B. Dumas. He had a wide circle of friends, and many young men of science owe him a deep debt of gratitude for the encouragement they received from him in their work. For a long time he suffered from a painful malady, and on the 15th of May he died at Paris, in his sixty-seventh year.

NOTES.

THE annual Ladies' *Conversazione* of the Royal Society will be held on Wednesday, June 6.

MR. R. G. HALIBURTON writes from Oran, Algeria, that a few hours after he had read the account in the *Times* of the recent *soirée* of the Royal Society, at which two skeletons of Akkas, sent by Emin Pasha from Equatorial Africa, were exhibited, the discovery, made by himself in February last, of the existence of another dwarf race, in North Africa, also only 4 feet high, and called by the same name, Akkahs, was confirmed by the receipt of a letter on the subject from our late Minister at Morocco, Sir John Drummond Hay.

THE creation of the new Chair of Philosophie Biologique is to be proposed to the Sorbonne in the course of the next few days. There will be much opposition to the scheme, but not enough to prevent it from being carried out.

THE ceremony in honour of Prof. Donders, at Utrecht, on Monday, passed off most successfully. Many friends and admirers, not only from all parts of Holland, but from the Dutch colonies and other countries, assembled to show their respect for the illustrious investigator, and the Dutch Government was represented on the occasion by the Home Minister. A medal commemorative of the ceremony was struck, and the King of Holland conferred on Prof. Donders the distinction of Commander of the Golden Lion. King Humbert sent him the Order of the Crown of Italy, and Sir Joseph Lister congratulated him on behalf of the Royal Society of England. In responding to the address recognizing his services to science and humanity, Prof. Donders declared that although the law rendered it necessary for him, on the attainment of his seventieth birthday, to resign his professorship, he did not consider that he had finished his task. The sum subscribed as an expression of gratitude for Prof. Donders' work is to be appropriated, in accordance with his own decision, for the benefit of young physiologists and ophthalmologists at the University.

DURING the recent cruise of the Liverpool Marine Biology Committee in the s.s. *Hyæna*, the electric light was applied to deep and surface tow-netting after dark with important results. We hope shortly to publish fuller details.

A MARINE zoological station, on the plan of the one at Naples, is shortly to be established at Ostend. The proposal is supported by four Belgian Universities.

A LETTER has been received by Sir J. D. Hooker from Mr. Joseph Thomson, dated Mogador, May 6, stating that he is on the eve of starting by a route through the province of Shedma to Saffi, where, after a short stay with M. Hunot, H.B.M.'s Consul there, he will go direct to Demenat, an entirely unexplored part of the Atlas, north-east of the city of Morocco. Mr. Thomson describes the past season as having been exceptionally late and cold, and with an extraordinary rain and snowfall; the season's rainfall at Mogador having been more than 32 inches, against an average of less than 18 inches.

IT is stated that Mr. Knipping, of the Meteorological Department of Japan, is coming to Europe on a mission to report on European meteorological observatories.

IN the *American Meteorological Journal* for April, Mr. A. L. Rotch continues his article on the history of the meteorological organizations, dealing with the German Institute, and the various newspaper services. Prof. F. Waldo contributes a very interesting paper on the instruments for making observations of the amount and direction of the wind. Special attention is given to Dr. Robinson's anemometer, as the instrument almost universally adopted, and so called from his investigation of its principle, published in 1850. Its invention is attributed to Edgeworth, who first used it as a scientific instrument, but a similar apparatus, made of wood, with oval cups, is described in the *Mongolische Völker*, 1770. Dr. Robinson found that the velocity of the cups must be multiplied by the factor 3 in order to get the true wind velocity, and this value was generally adopted. Mr. Stow and Prof. Stokes in this country, and Dr. Dohrandt in Russia, first questioned the accuracy of this value, and recent careful experiments by Mr. Dines, just communicated to the Royal Meteorological Society, show that the factor for anemometers of this class must be reduced to about 2·15. And further, it has been found that the formula for conversion of velocity to pressure ($P = \cdot005V^2$) adopted by Smeaton (Phil. Trans. 1763), and repeated subsequently in text-books, requires amendment, so that the pressures deduced from velocity anemometers have been greatly exaggerated. In fact great doubt has been expressed by competent authority as to the value of the records of this class of instruments. Prof. Waldo's discussion of the subject is therefore very opportune.

AT Cragside, Rothbury, Northumberland, the seat of Lord Armstrong, a very fine female of Pallas's sandgrouse (*Syrrhaptes paradoxus*) killed itself against the telegraph-wires near Cragside on Wednesday, May 23. The bird was picked up by the gamekeeper, and was sent by Lord Armstrong to Mr. John Hancock at the Natural History Museum, Newcastle-on-Tyne, where it will be carefully preserved. This bird was in fine plumage, and was proved by dissection to be a female, the ovary containing seven ova about the size of No. 1 shot, and numerous others of very much smaller size. It is a curious coincidence that the first specimens of Pallas's sand grouse, recorded in 1863, were shot at Thropton, a few miles west of Rothbury, on May 21, and were sent to Mr. Hancock. The crop of another specimen (male) of this bird, which we are told was obtained at Winlaton, five or six miles west of Newcastle-on-Tyne, was sent to the Museum on the 23rd inst. The crop was full of the seed of a wild plant, probably charlock or wild mustard (*Sinapis arvensis*, L.).

DR. TRIMEN'S report on the five Royal Botanic Gardens of Ceylon, which has just been issued, contains much interesting matter relating to the economic aid given by the institution to planting in Ceylon and elsewhere. Referring to the gradual decline in the cultivation of coffee, Dr. Trimen mentions, as one of the causes, that it has suffered severely during the last few years from the attacks of a scale-insect or "bug" which has in some places actually killed out the bushes. Practical planters think the insect different from either of the "bugs" familiar hitherto as foes to coffee—*Lecanium coffeæ* and *L. nigrum*, the brown coffee and black bugs. The distinctions between the three have been pointed out by Mr. E. Green in a paper with illustrations printed by the Government of Ceylon. He names the new pest *L. viride*, it being generally known as the green bug. Dr. Trimen mentions that his principal employment during the past year has been the compilation, with the aid of the library and herbarium, of a catalogue of the contents of the gardens, for use by the staff, the public, and correspondents in other countries. The list as now completed is brought down to the end of 1886, and contains about 3000 species, mostly trees and shrubs. He also reports the commencement of the long projected museum of economic botany.

A VOLUME on the life and works of Lavoisier, by Prof. E. Grimaux, of the Polytechnic School of Paris, has just been published. It is illustrated by many interesting engravings, two of which represent Lavoisier in his laboratory. A number of hitherto unknown documents relating to Lavoisier have been discovered by Prof. Grimaux.

MESSRS. MACMILLAN AND BOWES, Cambridge, will have ready in a week a "Bibliography of the Works of Sir Isaac Newton, together with a List of Books illustrating his Life and Works," by G. J. Gray.

MESSRS. MACMILLAN AND CO. will shortly publish a work on "The Theory and Practice of Absolute Measurements in Electricity and Magnetism," by A. Gray, M.A., Professor of Physics in the University College of North Wales. Though nominally a second edition of the small book by the same author published in 1884, it has been entirely re-written and extended in plan, so as to form a fairly complete treatise on the absolute measurement of electric and magnetic quantities. This has necessitated the division of the work into two volumes, of which the first, extending to over 450 pages, is about to be issued. The following is a synopsis of the contents :—Vol. I. contains a sketch of the theory of electro-statics and flow of electricity, chapters on units, general physical measurements, electrometers, comparison of resistances, comparison of capacities, and measurement of specific inductive capacities, and concludes with an appendix of tables of units, resistances, and useful constants. The chapter on the comparison of resistances contains full details of the various methods of comparing high and low resistances, calibration of wires, &c. ; the chapter on capacities discusses methods generally, and contains an account, as full as possible, of the principal determinations of specific inductive capacity made up to the present time. Vol. II. will contain an account of magnetic theory, units and measurements ; electro-magnetic theory and absolute measurement of currents, potentials and electric energy ; the definitions and realization of the ohm and other practical units ; the relations of electro-magnetic and electro-static units and the determination of v ; practical applications of electricity, and especially related points of theory and measurements. (This volume is in hand, and will be issued as soon as possible after Vol. I.) An attempt has been made to arrange the work so as to avoid any too sharp distinction between what is theoretical and what is practical, and at the same time preserve a logical order in the former and prevent the constant introduction of digressions on theory into accounts of instruments and processes of manipulation.

A WORK of some interest and importance, "Excursions zoologiques dans les Iles de Fayal et de San Miguel (Açores)," has just been producedby M. Jules de Guerne, at the expense of Prince Albert de Monaco. Of the new species mentioned, some, perhaps all, have been elsewhere recorded in contemporary periodicals. M. de Guerne concludes from his researches that the land fauna of the Azores has a definitely European character ; that the fresh-water fauna has the same character, many of the species composing it being probably cosmopolitan, most of them provided with powerful means of dissemination, which have enabled them to reach the Azores ; that most of the species have been brought by the wind and by birds, the wind playing only a secondary part ; that the lakes in the craters are of modern origin, due to the accumulation of rain-water, and have not taken long to people ; that the character of the aquatic types and the absence of any great struggle for existence suffice to explain this rapid peopling of the waters ; that the land species, like those of the water, have been fortuitously introduced from the nearest islands and continents, though at a remoter epoch and more distant intervals, this greater antiquity accounting for the greater differentiation of the land fauna, and in especial of the Mollusca; that the alpine character of the land fauna has not been demonstrated, and that, on the theory of the gradual submergence of the islands, the animals of the littoral region in retiring to the higher grounds would have there produced a varied and numerous assemblage of species, which, as a fact, is not found. Incidentally, M. de Guerne points out a mistake which has crept into works of importance—a sudden depth of 58 fathoms at a single spot being attributed to the little Lagoa Grande in the Island of San Miguel, instead of the true depth, which is about 17 fathoms.

THE Bancroft Company, San Francisco, announces that there will shortly be added to the series of guide-books to the Pacific Coast a hand-book of the Lick Observatory, which has been prepared by Prof. Edward S. Holden, Director of the Observatory. This book is intended to give all the information which will be of value to each one of the many visitors to the Lick Observatory, which possesses the largest and most powerful telescope in the world, and is situated in one of the wildest and most romantic portions of California. Besides the useful and necessary information of a mere guide-book, the work is to contain interesting and popular accounts of the various astronomical instruments, and of the way in which they are made and used. It will be illustrated by twenty or more woodcuts from photographs and drawings.

MR. HENRY BEDFORD, of All Hallows College, Dublin, writes to us :—"I see among the notes in your last number (p. 87) that Herr Sander, in his paper on some recently deciphered runic inscriptions in Sweden, says that 'in four of them appeared the word *Pim* or *Piment* (*i.e.* a strong drink composed of wine, honey, and spice), which, as well as *Klaret*, was mentioned in the *Saga* of Rollo the Ganger and the Normans,' and that 'all these inscriptions were referred to the close of the pagan age.' Now if the word *Klaret* refers like *Piment* to some kind of drink, does not this point to the direction in which we are to look for some more satisfactory explanation of our modern word *Claret* than that which our dictionaries give—as a derivation from the French *clairet*—although the word is not used in that language to describe the French wine to which we apply it. Perhaps you or some of your readers will throw some light upon the origin of this obscure word."

THE 800th anniversary of the University of Bologna will be celebrated on June 12 next. An oration will be delivered by the poet Giosué Carducci. There will also be a musical performance, an ode having been written for the occasion by Panzacchi, and set to music by Baron Franchetti.

Last week we printed a letter from M. Julius, of Delft, Holland, asking a question with regard to tables of reciprocals. Mr. T. S. Barrett and Mr. A. Freeman write to us recommending Barlow's tables of squares, cubes, square roots, cube roots, and reciprocals of all integers up to 10,000. The reciprocals are given to seven places of significant figures, besides the leading zeros. The work was edited by the late A. De Morgan, and published for the Useful Knowledge Society by Taylor and Walton, London, 1840.

Prof. Ball, General Director of the Science and Art Museum, Dublin, mentions in his report for 1887, that early in the year he brought before the Council of the Royal Irish Academy the desirability of its handing over to the Museum an old collection of moulds of Irish crosses and miscellaneous sculptures, together with casts, most of which had been prepared for the Exhibition of 1853. To this proposition the Academy cordially assented, and, after much piecing together of broken fragments, it was found that the material provided a very valuable and representative set of casts. It is proposed that casts of many objects of ancient Irish art not included in this collection shall also be obtained. The collection, when completed and properly arranged in the new Museum, ought to be of great service not only to archæologists but to workmen, who would be well rewarded for a careful and elaborate study of the ideas of the mediæval craftsmen of Ireland.

Herr H. Forsell has been chosen President of the Swedish Royal Academy of Science for the ensuing year, in place of Herr C. G. Malmström.

The Biological Society of University College will hold its annual *soirée* at the College on Thursday, June 7, beginning at 8 p.m. Prof. W. H. Flower, F.R.S., will deliver a lecture at 9 p.m. on "The Pygmy Races of Men." Tickets may be had on application to the secretaries of the Society.

We have received the *Annuaire* for the year 1888 of the Paris Society for the Encouragement of National Industry. Among the contents are a list of the members, and an extract from the programme relating to the prizes to be given by the Society from 1888 to 1893.

The Danish Government has granted a sum of £500 for the purpose of having the oyster-banks in Denmark examined by an expert. His object will be to ascertain the results of their continued preservation, with a view to the resumption of fishing.

Some months ago a large consignment of salmon ova was despatched from Denmark to Buenos Ayres, *viâ* Hamburg, for the stocking of certain lakes and rivers in the Argentine Republic. The experiment has proved very successful, the ova ariving in excellent condition, and further consignments are to be made.

The following incident in the trial of the great patent case, Edison and Swan Electric Light Company *v.* Holland and others, now proceeding in the Chancery Division of the High Court of Justice, before Mr. Justice Kay, is taken from the shorthand report in the *Electrician* of May 18. On May 16, Prof. James Dewar, F.R.S., Professor of Chemistry in the University of Cambridge was under examination. A small crucible was produced and handed to the witness, who said: In that crucible I have, with Mr. Gimingham, carbonized filaments in the precincts of the court, using no packing and no luting of any description. The filament was a thread so far as he could remember.

Sir Horace Davey urged that this did not arise out of the cross-examination.

Mr. Justice Kay said it should have been produced in the examination-in-chief. If it were pursued, Sir Horace Davey would be entitled to ask any questions upon it.

Sir Horace Davey, cross-examining:—About what heat was this produced at?—It was a mere experiment. It was a spirit-lamp that was used.

Do you suggest that this coil, or whatever you like to call it, has been heated to a sufficient heat for use as a conductor in an incandescent lamp? —Not at the present time.

Then it is not completely carbonized?—It is carbonized; but it does not conduct well enough. It wants to be heated for a longer time at a higher temperature.

Has it been heated to a degree at which the oxygen would combine with or attack the carbon?—That I cannot say. I think it is probably at a low red heat.

Mr. Justice Kay: I am very much disgusted. I am here trying all I can to understand the case, and this is clearly an attempt to mislead. I am greatly disgusted.

Prof. Dewar: I have no desire to mislead your lordship. I have stated that this was a mere experiment. I did not produce it. It was put to me.

Mr. Justice Kay: You may stand down.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Mr. George Somerford; a Barbary Ape (*Macacus inuus* ♀) from North Africa, presented by Miss Waterman; a Brazilian Tree Porcupine (*Sphingurus prehensilis*) from Pernambuco, presented by Mr. Clement J. Bateman; a Barbary Wild Sheep (*Ovis tragelaphus*), from North Africa, presented by Mr. E. H. Forwood; a Greater Black-backed Gull (*Larus marinus*), British, presented by Prof. E. Ray Lankester, F.R.S., F.Z.S.; a Herring Gull (*Larus argentatus*), British, presented by Mr. E. Wright: a Cape Dove (*Œna capensis*), a Tambourine Pigeon (*Tympanistria bicolor*) from South Africa, presented by Mr. R. H. Milford; a White-handed Gibbon (*Hylobates lar*) from the Malay peninsula, a Chimpanzee (*Anthropopithecus troglodytes* ♀), a Marabou Stork (*Leptoptilus crumeniferus*) from West Africa, two Caracals (*Felis caracal juv*) from Africa, three Red-crowned Pigeons (*Erythrœnas pulcherrimus*), a Praslin Parrot (*Coracopsis barklyi*), two —— Kestrels (*Tinnunculus gracilis*) from the Seychelles, a Laughing Kingfisher (*Dacelo gigantea*), a Black-backed Piping Crow (*Gymnorhina tibicen*), a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, two Glass Snakes (*Pseudopus pallasi*) from Dalmatia, deposited; six Common Pintails (*Dafila acuta*), eight Common Teal (*Querquedula crecca*), eight Garganey Teal (*Querquedula circia*), ten Wigeon (*Mareca penelope*), a Shoveller (*Spatula clypeata*), British, purchased; a Red Kangaroo (*Macropus rufus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Comet 1888 *a* (Sawerthal).—At the beginning of last week, apparently on May 20 or 21, the comet suddenly became very much brighter, gaining fully three magnitudes. It has since faded again. Only a few observations have as yet come to hand, but it is to be hoped that everyone who has observed it during the last fortnight, and made any estimate of its brightness, will publish his observations without delay.

The Short Period Comets and Asteroids.—Prof. Kirkwood, who has already given reasons for thinking that two short period comets originally belonged to the group of asteroids, has extended his argument in the *Sidereal Messenger* for May to include the class of short period comets as a whole. He points out that, of the twenty comets concerned, seven have disappeared, either by dissolution into fragments, like Biela's comet, or by the transformation of the orbit by the influence of Jupiter, as in the case of Lexell's comet. The instances of the comets of Lexell and Wolf (1884) are representative, Prof. Kirkwood considers, of the mode in which asteroidal may have been changed into cometary orbits. Had the latter, indeed, been discovered before its perturbation, it would probably have been considered simply an asteroid of unusually long period, for its eccentricity and inclination were well within asteroidal limits. Of the twenty comets, not only have seven disappeared, but five, or, including Encke's and Biela's, seven, have periods commensurable with that of Jupiter; all the twenty have direct motion; all but one have smaller inclination than Pallas; and, as with the asteroids, there is a tendency of the perihelia to concentrate in the 180° from 290° to 110°.

NEW MINOR PLANET.—A new minor planet was discovered by M. Borrelly on May 12 at Marseilles. This may possibly, but not very probably, prove to be Xanthippe, No. 156. Should it be really a fresh discovery, it will rank as No. 278, whilst the one discovered by Herr Palisa on May 16 (see NATURE, vol. xxxviii. p. 89) will be numbered 279.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *JUNE* 3-9.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 3

Sun rises, 3h. 49m.; souths, 11h. 57m. 57·6s.; sets, 20h. 7m.: right asc. on meridian, 4h. 47·4m.; decl. 23° 24′ N. Sidereal Time at Sunset, 12h. 58m.

Moon (New on June 9, 17h.) rises, 1h. 42m.; souths, 7h. 30m.; sets, 13h. 29m.: right asc. on meridian, 0h. 18·6m.; decl. 2° 54′ S.

GEOGRAPHICAL NOTES.

IN the Report of the Survey of India for 1886–87, Colonel Strahan gives an account of the survey and exploration of the Nicobar Islands by himself and party. A very careful survey of the whole group was made, and the coast-lines at last accurately laid down. Owing to the dense vegetation, the party were unable to penetrate any distance into the interior, and only a few heights could be measured. The culminating point of the whole group, 2105 feet above sea-level, stands near the south-east corner of Great Nicobar, the area of which is 375 square miles, the total area of the group being 678 square miles. The scenery, especially of Great and Little Nicobar, is of indescribable beauty. There are several rivers in the former island which are navigable by boats for some miles, especially the Galatea, on the south coast. Its course is very tortuous, the banks are fringed with tree-ferns, canes, bamboos, and tropical vegetation of infinite variety, through which occasional glimpses are obtained of high mountains in the interior covered with dense forests to their very summits, and generally cloud-capped. The country through which the stream runs is almost uninhabited; a few huts appear here and there tenanted by an inland tribe of savages called "Shom Pen," of whom very little is known, except that they are in such an utter state of barbarism as to be held in contempt even by the Nicobarese inhabiting the coasts. On most of the islands the forest grows luxuriantly down to the beach. Mangroves, except in the island of Kamorta, are not very plentiful, and in this respect these islands differ widely from the neighbouring Andaman group, where the creeks are fringed with mangroves mile after mile. The sea-beach consists largely of coral. The climate is very equable day and night all the year through, and most pleasant to one's feelings, but unfortunately its character for unhealthiness is only two well established. The rainfall, which averages about 100 inches, is pretty evenly distributed throughout the year. The thermometer stands very steadily between 80° and 85° in the shade, and hardly varies day or night. The inhabitants of these islands, Colonel Strahan states, are allied to the Malays, and are a complete contrast to their tiny, intensely black, woolly-haired neighbours, the Andamanese. The Nicobarese are very strong, thickly-built men, not much if at all inferior to Europeans in physique, of a reddish-brown colour. They are unconquerably lazy, having no inducement whatever to exertion. They have a wonderful talent for learning languages. Fortunately, Mr. Man, the Settlement Officer at Kamorta, who has done so much for Andaman anthropology, has been carefully studying the Nicobarese, their habits and language, and is now engaged on a book on the subject, which will shortly be published.

MR. C. M. WOODFORD, the successful naturalist explorer of the Solomon Islands, is about to leave England on a third visit to the group. After spending some time in various parts of the islands not previously visited, he will investigate Santa Cruz, Woodlark Island, and other islands lying to the south-east of New Guinea.

ACCORDING to the new Survey Report, triangulation surveys have already been effected over 15,000 square miles in Upper Burma, and the out-turn of reconnaissance surveys amounts to 11,000 square miles on the scale of 4 miles to an inch, in the following States and districts: Northern Shan States and Ruby Mines district, 3000 square miles; Southern Shan States, 3000; Yemethin and Mehtila district, 2000; Yaw country, 1000; Mandalay and Kyaukse districts, 2000.

IN the summary Report of the Geological Survey of Canada for 1887, some of the results are given of the expedition under Dr. G. M. Dawson last summer, of the exploration of British Columbia. Mr. Ogilvie's instrumental survey to the intersection of the Yukon with the 141st meridian will form a sufficiently accurate base-line for future explorations in this region. In addition to this the geographical results include the completion of an instrumental survey of the Sitkine to Telegraph Creek by Mr. McConnell, which is connected with Dease Lake by a carefully placed traverse by Mr. M'Evoy. Thence a detailed running survey was carried by the Dease, Liard, and Pelly Rivers, connecting with Mr. Ogilvie's line at the mouth of the Lewis River, a total distance of 900 miles. Taken in conjunction with Mr. Ogilvie's line, these surveys include an area of over 6000 square miles, the interior of which is still, with the exception of reports received from a few prospectors and from Indians, a *terra incognita*. The same remark may be applied to the whole surrounding region outside the surveyed circuit, but much general information has been obtained respecting the entire district, which will facilitate further explorations. The whole region is more or less mountainous, though intersected by wide areas of flat or valley country. The country, though generally mountainous in character, includes large tracts of flat and slightly broken land, and, according to Dr. Dawson, may eventually support a population as large as that found in corresponding latitudes in Europe.

THE anniversary meeting of the Royal Geographical Society was held on Monday in the hall of the University of London, General R. Strachey presiding. The report, which was read by Mr. Clements R. Markham, having been adopted, General Strachey was for the third consecutive year elected President of the Society. The Founder's Medal for the encouragement of geographical science and discovery was presented to Mr. Clements R. Markham, who retires from the honorary secretaryship after twenty-five years' service, in acknowledgment of the valuable services rendered by him to the Society during that period. Lieut. H. Wissmann was awarded the Patron's Medal in recognition of his great achievements as an explorer in Central Africa; Mr. J. M'Carthy, Superintendent of Surveys in Siam, the Murchison Grant; Major Festing, the Cuthbert Peek Grant, for his services as a cartographer on the Gambia River and the country in the neighbourhood of Sierra Leone. The Gill Memorial for 1888 was secured by Mr. Charles M. Doughty. Various scholarships and prizes to students in training colleges were also distributed. The President then delivered his annual address, passing in review the chief geographical events of the year.

THE LINNEAN SOCIETY.

THE hundredth anniversary meeting of this Society was held on Thursday last, 24th inst., at Burlington House, in the library, the usual meeting-room being inadequate for the reception of the large number of members present on this occasion. The President, Mr. Wm. Carruthers, F.R.S., took the chair at three o'clock, and was supported by the two former Presidents who are happily still with us—Prof. Allman and Sir John Lubbock—the Council of the Society, and many distinguished Fellows, amongst whom we noted Sir Richard Owen, Sir Joseph Hooker, Dr. Günther, Sir Walter Buller, Prof. Duncan, Mr. Romanes, Colonel Grant, and amongst the visitors Dr. Henry Woodward, F.R.S., and Mr. Studley Martin, a nephew of the founder.

After preliminary business, H.M. the King of Sweden was elected an honorary member. The Treasurer, Mr. Frank Crisp, laid the last year's accounts before the meeting, and briefly referred to the financial history of the Society during the century now closed. The senior Secretary, Mr. B. Daydon Jackson, presented an account of the Linneau collections from their formation, their purchase by the founder of the Society, and their possession by the Linnean Society. This was succeeded by the President's annual address, which was largely devoted to a review of the Society's past career. He spoke of the original quarto Transactions, then of the octavo Proceedings, finally of the Journal, of which forty-three volumes are extant. During the past year seven parts of the Transactions and twenty of the Journal had been issued, an amount equal to that published during fifteen years in the early part of the century.

A novel feature was then introduced, one of those intended to mark the centenary of the Society. Prof. Thöre Fries, the present occupant of Linnæus's Botanical Chair at Upsala, had been invited to pronounce a eulogium on his illustrious predecessor. As he was detained by his professorial duties in his University, his essay was read by the President. In it he spoke of the profound sleep of natural science during the Middle Ages, and the hard struggle which had to be fought before men of science could liberate themselves from a narrow orthodoxy, or the fetters they had themselves forged by attaching infallibility to Aristotle and classic authors. Linnæus bore an honourable part in placing the study of natural science on a logical basis by his clear definitions, and admirable nomenclature, and by the enthusiasm he was able to rouse in his disciples for the same methods. England, unluckily for Sweden, became his heir; many consequently are the ties which unite the memory of Linnæus with this country, the strongest perhaps being the Linnean spirit, the genuine spirit of freshness and enterprise in which scientific research is carried on in England.

Sir Joseph Hooker then pronounced a eulogy on Robert Brown, the greatest botanist of the present century. He specially dwelt on the evidence afforded by the "Prodromus" of his untiring industry, accuracy of observation and exposition, together with sagacity, caution, and soundness of judgment, in which he has not been surpassed. Where others have advanced beyond the goal he reached, it has been by working on the foundations he laid, aided by modern appliances of optics and physics. His memory was wonderful, he seemed never to forget a plant he had examined; and the same with his books—he could turn to descriptions for a statement or a figure without needing a reference. The noble title conferred upon him by Humboldt has been confirmed by acclamation by botanists of every country, "Botanicorum facile princeps."

Prof. Flower, C.B., F.R.S., delivered an address on Charles Darwin, who, he said, had special claims on their consideration, inasmuch as a large and very important portion of his work was communicated to the world by papers read before the Society and published in the Journal. His life was one long battle against our ignorance of the mysteries of living Nature, and he sought to penetrate the shroud which conceals the causes of all the variety and wonders round us. His main victory was the destruction of the conception of species as being fixed and unchangeable beyond certain narrow limits, a view which prevailed universally before his time. That other factors had operated besides natural selection in bringing about the present condition of the organic world was admitted even by Darwin himself. His work, and the discussions which had sprung from it, had marvellously stimulated research, and he had shown by his life and labours the true methods by which alone the secrets of Nature may be won.

Prof. W. T. Thiselton Dyer spoke on George Bentham, who presided over the Society from 1863 to 1874. A nephew of Jeremy Bentham, and trained to some extent under him, he was early imbued with a taste for method and analysis, and through his mother's fondness for plants he was led to study them, with marvellous results. The records of his life-work are astonishing. Whilst President he delivered a series of masterly addresses, and the latter part of his career witnessed the preparation of the "Flora Australiensis" and a full share of the "Genera Plantarum." He stood in the footsteps of Linnæus, and although the descent was oblique he inherited the mantle of the master whose memory was that day commemorated.

The President stated that the Council had decided to establish a Linnean Gold Medal, to be presented to a botanist and a zoologist in alternate years, but on this occasion it would be awarded in duplicate. The medal bore on the obverse a profile of Linnæus, modelled from the bust in the library; on the reverse, the arms of the Society and the name of the recipient. The President made the first presentation to Sir Richard Owen, recounting the chief services he had rendered to zoology. Sir Richard, with some emotion, expressed his high sense of the honour conferred, and thanked the Fellows for their cordial reception of him. The President then presented a similar medal to Sir Joseph Hooker, with a like recapitulation of the splendid services he had bestowed on botany. Sir Joseph suitably replied, returning his cordial thanks for the distinction.

The remaining formal business included the announcement of the newly-elected Councillors, and the re-election of the officers—Mr. Wm. Carruthers, President; Mr. Frank Crisp, Treasurer; and Messrs. B. Daydon Jackson, and W. Percy Sladen, Secretaries.

The annual dinner was held at the Hotel Victoria, Northumberland Avenue, at seven o'clock. The President took the chair, about sixty of the Fellows being present. In addition to the usual toasts, that of "The Medallists" was given, and replied to by Sir Joseph Hooker, who alluded to the fact that he had personally known eight of the Presidents of the Society, and that the founder himself induced his father, Sir William Hooker, to take up the study of botany. As a proof of his close connection with the Linnean Society, he added that his father, grandfather, father-in-law, and uncle had all been Fellows.

The final portion of the centenary celebration took place the following evening, when the President and officers held a reception at Burlington House. A special feature was made of the Linnean manuscripts and memorials, which were displayed in glass cases with descriptions, a catalogue of them being also distributed. Memorials of other distinguished naturalists were also shown, conspicuously those of Robert Brown and George Bentham, lent by Sir Joseph Hooker and M. Alphonse de Candolle, of Geneva, a foreign member of the Society.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Rede Lecture on June 8, by Sir F. A. Abel, will be upon applications of science to the protection of human life. It will be illustrated by experiments and the exhibition of appliances.

Mr. Percy Groom, B.A., late of Trinity College, has been elected to the Frank Smart Studentship in Botany at Gonville and Caius College.

The fittings of the new Chemical Laboratory are costing £1000 more than was originally estimated (from rough drawings only) by Mr. Lyon, Superintendent of the University workshops. Some of this is due to the fact that the fixing of the tables on a bottom independent of the floors of the rooms, and making the cupboard doors fairly dust-proof, originally recommended, was not adopted till after the tables had been fixed, and much cutting of the floors had to be done. Also much of the iron and steel work was not particularized at first.

The Council are taking steps to carry out the appropriation of the old Chemical Laboratory to the department of pathology.

Prof. Darwin will lecture during the long vacation on the theory of the potential, and on attractions, commencing on Tuesday, July 10. The lectures will treat principally of gravitational problems, including attraction of ellipsoids, Gauss's paper, heat of tin, Jacobi's and Dedekind's ellipsoids, oscillations of a fluid sphere, the foundation of the theory of tides, atmospheres of planets, &c.

SOCIETIES AND ACADEMIES.

London.

Royal Society, May 3.—"Effect of Chlorine on the Electromotive Force of a Voltaic Couple." By Dr. G. Gore, F.R.S.

If the electromotive force of a small voltaic couple of unamalgamated magnesium and platinum in distilled water, is balanced through the coil of a moderately sensitive galvanometer of about 100 ohms resistance, by means of that of a small Daniell's cell, plus that of a sufficient number of couples of iron and German silver of a suitable thermo-electric pile (see Proc. Birm. Philos. Soc., vol. iv. p. 130), the degree of potential being noted; and sufficiently minute quantities of very dilute chlorine water are then added in succession to the distilled water, the degree of electromotive force of the couple is not affected until a certain definite proportion of chlorine has been added; the potential then suddenly commences to increase, and continues to do so with each further addition within a certain limit. Instead of making the experiment by adding chlorine water, it may be made by gradually diluting a very weak aqueous solution of chlorine.

The minimum proportion of chlorine necessary to cause this sudden change of electromotive force is extremely small; in my experiments it has been 1 part in 17,000 million parts of water,[1] or less than 1/7000 part of that required to yield a barely perceptible opacity in ten times the bulk of a solution of sal-ammoniac by means of nitrate of silver. The quantity of liquid required for acting upon the couple is small, and it would be easy to detect the effect of the above proportion, or of less than one ten-thousand-millionth part of a grain of chlorine, in one-tenth of a cubic centimetre of distilled water by this process. The same kind of action occurs with other electrolytes, but requires larger proportions of dissolved substance.

As the degree of sensitiveness of the method appears extreme, I add the following remarks. The original solution of washed chlorine in distilled water was prepared in a dark place by the usual method from hydrochloric acid and manganic oxide, and was kept in an opaque well-stoppered bottle in the dark. The strength of this liquid was found by means of volumetric analysis with a standard solution of argentic nitrate in the usual manner, the accuracy of the silver solution being proved by means of a known weight of pure chloride of sodium. The chlorine liquid contained 2·3 milligrammes or 0·03565 grain of chlorine per cubic centimetre, and was just about three-fourths saturated.

One-tenth of a cubic centimetre of this solution ("No. 1"), or 0·003565 grain of chlorine, was added to 9·9 c.c. of distilled water and mixed. One cubic centimetre of this second liquid ("No. 2"), or 0·0003565 grain of chlorine was added to 99 c.c. of water and mixed; the resulting liquid ("No. 3") contained 0·000003565 grain of chlorine per cubic centimetre. To make the solutions ("No. 4") for exciting the voltaic couple, successive portions of $\frac{1}{10}$ or $\frac{1}{20}$ c.c. of ("No. 3") liquid were added to 900 cubic centimetres of distilled water and mixed.

[1] As 1 part of chlorine in 17612 million parts of water had no visible effect, and 1 in 17000 millions had a distinct effect, the influence of the difference, or of 1 part in 500,000 millions, has been detected.

I have employed the foregoing method for examining the states and degrees of combination of dissolved substances in electrolytes, and am also investigating its various relations.

May 17.—"Magnetic Qualities of Nickel." By J. A. Ewing, F.R.S., Professor of Engineering, University College, Dundee, and G. C. Cowan.

The experiments described in the paper were made with the view of extending to nickel the same lines of inquiry as had been pursued by one of the authors in regard to iron (Phil. Trans., 1885, p. 523). Cyclic processes of magnetization have been studied, in which a magnetizing force of about 100 C.G.S. units was applied, removed, reversed, again removed, and re-applied, for the purpose of determining the form of the magnetization curve, the magnetic susceptibility, the ratio of residual to induced magnetism, and the energy dissipated in consequence of hysteresis in the relation of magnetic induction to magnetizing force. Curves are given, to show the character of such cycles for nickel wire in three conditions: the original hard-drawn state, annealed, and hardened by stretching after being annealed. The effects of stress have also been examined (1) by loading and unloading magnetized nickel wire with weights which produced cyclic variations of longitudinal pull, and (2) by magnetizing while the wire was subjected to a steady pull of greater or less amount. The results confirm and extend Sir William Thomson's observation that longitudinal pull diminishes magnetism in nickel. This diminution is surprisingly great: it occurs with respect to the induced magnetism under both large and small magnetic forces, and also with respect to residual magnetism. The effects of stress are much less complex than in iron, and cyclic variations of stress are attended by much less hysteresis. Curves are given to show the induced and residual magnetism produced by various magnetic forces when the metal was maintained in one or other of certain assigned states of stress; also the variations of induced and residual magnetism which were caused by loading and unloading without alteration of the magnetic field. Values of the initial magnetic susceptibility, for very feeble magnetizing forces, are stated, and are compared with the values determined by Lord Rayleigh for iron, and the relation of the initial susceptibility to the stress present is investigated. The paper consists mainly of diagrams in which the results are graphically exhibited by means of curves.

Chemical Society, May 3.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—The determination of the molecular weights of the carbo-hydrates, by Mr. H. T. Brown and Dr. G. H. Morris. The law established by Blagden in 1788, that the lowering of the freezing-point of aqueous solutions of inorganic salts is proportional to the weight of substance dissolved in a constant weight of water, was extended by de Coppet in 1871–72, who pointed out that when the lowering of the freezing-point is calculated for a given weight of the substance in 100 grammes of water, the result, which he termed the coefficient of depression, is constant for the same substance, and that the coefficients for different substances bear a simple relation to their molecular weights. Raoult extended the law to organic substances and to other solvents than water, and showed that when certain quantities of the same substance are successively dissolved in a solvent upon which it has no chemical action, there is a progressive lowering of the point of congelation of the solution, and that this lowering is proportional to the weight of the substance dissolved in a constant weight of water. The "coefficient of depression," A—that is, the depression of the point of congelation produced by 1 gramme of the substance in 100 grammes of the solvent—is given by the formula $\frac{C \times y}{x \times 100} = A$, where C is the observed depression produced by x grammes of the substance dissolved in y grammes of the solvent, and from this value the "molecular depression," T, is calculated by the formula $M \times A = T$, where M is the molecular weight of the substance in question. T is a value varying with the nature of the solvent, but remaining constant with the same solvent for numerous groups of compounds, whence it follows that A and T being known, the molecular weight of the substance in question may be determined from the equation $M = T/A$. This method of Raoult's, which is of value in cases where a vapour density determination is not possible, has been employed by the authors to determine the molecular weights of the following carbo-hydrates: dextrose, cane-sugar, maltose, milk-sugar, arabinose, and raffinose, and also that of mannitol (the solvent being water), with results which lead to formulæ identical with those ordinarily adopted for these substances.—The molecular weights of nitric peroxide and nitrous anhydride, by Prof. Ramsay. The molecular weight of nitric peroxide as determined by Raoult's method in acetic acid solution, accords with the formula N_2O_4. No definite results could be obtained with nitrous anhydride since dissociation occurred at the temperature of experiment (16°).—In the discussion which followed the reading of these papers, and in which Prof. Debus, F.R.S., Dr. Perkin, F.R.S., and others took part, Mr. Wynne remarked that most results hitherto obtained by Raoult's method pointed to a complete dissociation of the complex molecules present in solids and liquids, and would seem to show that the dissociation is not dependent on the particular solvent employed; Mr. Crompton referred to the great irregularities noticeable on comparing the molecular depressions of various substances as determined by Raoult, and thought that until more was known of the cause of such irregularities, and of the mechanism of the changes under discussion, such results as those brought forward by Messrs. Brown and Morris should be accepted with great reservation; and Prof. Armstrong, F.R.S., observed that, apart from the information as to the comparative molecular weights of dissolved substances which Raoult's method promised to afford, it appeared that, in order to gain as complete an insight as possible into the molecular composition of solids and liquids it was important to vary in every way the proportions of substance dissolved as well as the solvent.—The action of heat on the salts of tetramethylammonium, by Dr. A. T. Lawson and Dr. N. Collie. In the majority of cases, the salts examined decompose in a simple manner, yielding trimethylamine and a salt of methyl.—The action of heat on the salts of tetramethylphosphonium, by Dr. N. Collie. The salts of tetramethylphosphonium with the oxy-acids, when heated, undergo as a rule two changes: the first and most important is the production of trimethylphosphine oxide and a ketone, and the second, which occurs only to a very limited extent, results in the formation of trimethylphosphine and a salt of methyl.

Geological Society, May 9.—Mr. W. T. Blanford, F.R.S. President, in the chair.—The following communications were read:—The Stockdale Shales, by J. E. Marr, and Prof. H. A. Nicholson. The Stockdale Shales extend in an east-north-east to west-south-west direction across the main part of the Lake District, parallel with the underlying Coniston Limestone Series and the overlying Coniston Flags, with both of which they are conformable. They also occur in the neighbourhood of Appleby, and in the Sedbergh district. They are divisible into a lower group of black and dark gray and blue Graptolite-bearing shales, interstratified with hard bluish-gray mudstones, containing Trilobites and other organisms, and an upper group of pale greenish-gray shales, with thin bands of dark Graptolitic shales. The lower group (Skelgill Beds) are well seen in the stream which runs past Skelgill Farm, and enters Windermere near Low Wood; while the upper group (Browgill Beds) occurs fully developed in the Long Sleddale Valley, and its beds are very fossiliferous in Browgill. The authors divided these into a series of fossil-zones, and the beds were compared with the corresponding beds in Sweden, Bohemia, Bavaria, &c. The fossils other than Graptolites were shown to occur elsewhere in strata of Llandovery-Tarannon age, from which it was concluded that the Stockdale Shales occupy that horizon. A fault occurs everywhere between the Middle and Lower Skelgill Beds, except perhaps in the Sedbergh district; but it does not seem to cut out a great thickness of rock, and the authors gave reasons for supposing that it was produced by one set of beds sliding over the other along a plane of stratification. The beds are found to thicken out in an easterly direction, and the possibility of the existence of land in that direction was suggested. The authors directed attention to the importance of Graptolitoidea as a means of advancing the comparative study of the stratified deposits of Lower Palæozoic age. A description was given of the following new species and varieties:—*Phacops elegans*, Boeck and Stars, var. *glaber*, *Cheirurus bimucronatus*, Murch., var. *acanthodes*, *Cheirurus moroides*, *Acidaspis erinaceus*, *Harpes judex*, *H. angustus*, *Ampyx aloniensis*, *Proëtus brachypygus*, and *Atrypa flexuosa*.—On the eruptive rocks in the neighbourhood of Sarn, Caernarvonshire, by Alfred Harker.

Zoological Society, May 1.—Prof. Flower, F.R.S., President, in the chair.—Colonel Irby exhibited (on behalf of Lord Lilford) a specimen of *Aquila rapax* from Southern Spain, believed to be the first authentic specimen of this species known from the Peninsula.—Prof. Flower exhibited and made remarks on a specimen of the Japanese Domestic Fowl with the tail-coverts enormously elongated, the longest attaining a length of 9 feet. The specimen had been presented to the British Museum by Mr. F. D. Parker.—Mr. C. M. Woodford made some general remarks on the zoology of the Solomon Islands, and read some notes on the nesting-habits of Brenchley's Megapode, which lays its eggs in the sands on the sea-shore of these islands.—Mr. G. A. Boulenger read the description of a new Land-Tortoise of the genus *Homopus* from South Africa, based on specimens living in the Society's Gardens, which had been presented to the Society by the Rev. G. H. R. Fisk. The author proposed to name the species *H. femoralis*.—Mr. F. E. Beddard read the second of his series of notes on the visceral anatomy of birds. The present paper treated on the air-sacs in certain diving birds.—Mr. Francis Day read the first of a proposed series of observations on Indian fishes.

Royal Meteorological Society, April 18.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—Jordan's new pattern photographic sunshine recorder, by Mr. J. B. Jordan. The improvement in this instrument over the previous pattern of sunshine recorder consists in using two semi-cylindrical or D-shaped boxes, one to contain the morning, and the other the afternoon chart. An aperture for admitting the beam of sunlight is placed in the centre of the rectangular side of each box so that the length of the beam within the chamber is the radius of the cylindrical surface on which it is projected; its path therefore follows a straight line on the chart at all seasons of the year. The semi-cylinders are placed with their faces at an angle of 60° to each other. They are fixed on a flat triangular plate which is hinged to a suitable stand having levelling screws attached, and fitted with a graduated arc as a means of readily adjusting and fixing the cylinders to the proper vertical angle agreeing with the latitude of the station where used.—On the meteorology of South-Eastern China in 1886, by Dr. W. Doberck. This paper gives the results of observations made at the Custom-houses and lighthouses by officers of the Imperial Chinese Maritime Customs. In summer there is very little change of temperature with latitude. The temperature depends upon the distance from the nearest sea coast, and is greatest at stations farthest inland. The highest mean temperature occurred in July, and the lowest in January. The north-east monsoon blows from September to June, and the south monsoon during July and August; the latter does not blow with half the force of the former. Rainfall is greatest in Northern Formosa, and least in Northern China. Along the east coasts of Formosa and Luzon the winter is the wet season, while in China July seems to be the wettest month of the year.—Lightning in snowstorms, by Prof. A. S. Herschel, F.R.S.—Insolation, by Mr. Rupert T. Smith.

EDINBURGH.

Royal Society, May 7.—Lord Maclaren, Vice-President, in the chair.—Dr. G. Sims Woodhead communicated a paper written by Mr. Robert Irvine and himself, on the secretion of carbonate of lime by animals.—A paper by Mr. Irvine and Mr. George Young, on the solubility of carbonate of lime under different forms in sea-water, was also read.—Dr. Alexander Bruce described a case of absence of the *corpus callosum*, in the human brain.—Dr. J. Murray discussed the distribution of some marine animals on the west coast of Scotland.—Mr. W. E. Hoyle described some larvæ of certain Schizopodous Crustacea from the Firth of Clyde.

May 21.—The Rev. Prof. Flint, Vice-President, in the chair.—A series of photographs of the Nice Observatory, presented by M. Bischoffsheim through the Astronomer-Royal for Scotland, were exhibited.—A note by Prof. Cayley, on the hydrodynamical equations, was communicated. The author discusses the result of the elimination of the symbol denoting the pressure by differentiation of the three fundamental hydrokinetical equations.—Dr. Archibald Geikie treated fully the history of volcanic action during Tertiary time in the British Islands.

PARIS.

Academy of Sciences, May 22.—M. Janssen, President, in the chair.—Obituary notice of M. Hervé Mangon, member of the Section for Rural Economy, and Vice-President of the Academy for the year 1888, by the President. M. Mangon, who was born in Paris on July 31, 1821, and died there on

May 15, 1888, may be regarded as the founder of agronomic science, to which he devoted many years of assiduous labour. To him France is indebted for the introduction of all the more useful agricultural processes. He also gave a great stimulus to the associated science of meteorology, and rendered important services to ballooning, especially in connection with military tactics.—On the part played by atmospheric nitrogen in vegetable economy, by M. E. Chevreul. A few summary observations are made in reference to the memoir recently presented to the Academy by MM. Gautier and Drouin. These observers having announced as a result of their personal experiments and as something new to science that the gaseous nitrogen of the atmosphere is absorbed by plants, it is pointed out that the Commission appointed in 1854 to investigate the question decided in favour of M. Georges Ville's theory and against that of M. Boussingault. Since then the part played by atmospheric nitrogen in the vegetative process has been carefully studied both in France and Germany, and hitherto the results, such as those of MM. Gautier and Drouin, have tended to confirm the conclusions first arrived at by M. Georges Ville.—The sardine on the Marseilles coast, by M. A. F. Marion. The sardine appears yearly in these waters, where a total of 409,055 kilogrammes were taken during the period between March 1887 and the end of February 1888. Details are given regarding the food, migrations, and breeding-season of this fish.—Study of the planet Mars, by M. F. Terby. Three small round spots, white and brilliant, are visible on the continuation of *Erebus* (left or west side), when the *Trivium Charontis* is midway from the central meridian in the eastern half of the disk. These spots, at first scarcely perceptible, become brighter and whiter as they approach the limb, where they become diffused by irradiation like the polar spot. The black line, which seems to divide the north polar spot, has been perfectly visible since May 12. Facing it on the outer side is a small hyperborean tract, white or snowy, but less brilliant and white than the true polar spot, of which it seems at first sight to form an integral part. It is evidently the same phenomenon as that which has recently been simultaneously observed by M. Perrotin, as well as by M. Schiaparelli.—On an electro-chemical actinometer, by MM. Gouy and H. Rigollot. Copper oxidized or covered with basic salts, and plunged into water or into a solution of sulphate of copper, is known to undergo variations of electromotor force under the action of light, effects which can be clearly indicated only with intensely luminous means. But the authors find that the oxidized copper plunged into a solution of metallic chloride, bromide, or iodide becomes, on the contrary, extremely sensitive to luminous rays even of slight intensity, and may consequently be employed as an actinometer. Details are given of the process by which they have constructed the apparatus based on this phenomenon.—Determination of the heat of combustion of a new solid substance isomerous with benzine, by M. W. Louguinine. Five experiments with a beautiful specimen of this substance, discovered by M. Grimer, give a mean of 10,863·9 calories for the heat liberated in the combustion of 1 grain. The heat of combustion of benzine is much less (776,000 cal.), corresponding to a body whose constitution is absolutely different from that of the isomerous substance.—On the Pliocene formations of the Montpellier district, by M. Viguier. In this paper the conclusions are summed up of an extensive investigation of this geological area. Three distinct groups are determined: (1) Arnusian, fresh-water deposits, puddings and gravels, with remains of *Elephas meridionalis*; (2) Astian, also fresh-water, clays and marls, with remains of *Semnopithecus monspessulanus*, *Helix quadrifasciata*, *Triptychia sinistrorsa*, &c.; (3) Plaisancian, marine deposits, sandy and other marls, with remains of *Potamides basteroti*, *Melampus myotis*, *Rhinoceros leptorhinus*, *Mastodon brevirostris*, &c.

BERLIN.

Meteorological Society, May 1.—Dr. Vettin, President, in the chair.—Dr. Perlewitz spoke on aperiodic variations of temperature. He based his researches on the observations made at Berlin during the forty years 1848–87, and during ninety-three years, 1791–1883, at Breslau. If a year is divided into halves, the first half is characterized by a normal curve of rising temperature, the second half by a similarly normal curve of falling temperature. Both curves, however, show negative irregularities, whose number may be very considerable in any one month: thus in May these irregularities (fall of temperature) occurred on more than thirteen days as against seventeen days on which the curve rose regularly; and similarly, in October, there were more than twelve days on which an irregularity (rise of temperature) was observed as against nineteen days with a normally falling temperature. On the whole the number of these irregularities is greater in the first half of the year than in the second, so that the heat of the second half is greater than that of the first. A whole series of interesting details exists in connection with the number, magnitude, and periodic duration of the changes of temperature during both the normal and abnormal times; these cannot however be considered here.—Dr. Vettin communicated the results of his observations on the daily periodicity in the velocity of the wind, extending over a period of two years. From direct determination of the movement of smoke coming from a chimney, and from observations with a home-made anemometer, he found that in addition to the well-known maximum velocity of the wind which occurs at midday, there is a second maximum just after midnight. This latter maximum is very small in summer, but in winter, on the other hand, it is much greater and even exceeds that maximum which occurs at midday. This second maximum is not very marked as an average on the whole year. The speaker then gave a detailed description of the construction of his anemometer, which he exhibited to the Society. He further described a spring vane which he had made, which he has erected at the window of his house in a moderately wide street; this vane indicates accurately not only the direction of the wind which is blowing up or down the street, but also of any wind which may be blowing over the houses at right angles to this. Experiments made with tobacco-smoke in a glass-covered chamber have shown that the wind which blows over the houses gives rise to ascending and descending currents of air along their walls, causing an elevation or depression of the vane. The vane also records accurately the direction of a wind which blows at any angle other than at right angles to the axis of the street. Suitable as this spring vane is for observers who live in narrow streets, it is specially adapted for observations in narrow mountain valleys, in which the direction of the wind cannot be ascertained by any other means.

Physical Society, May 4.—Prof. von Bezold, President, in the chair.—Prof. Schwalbe gave expression to the loss which the Society had sustained through the death of Prof. Hoh, for many years an active collaborator with the "Fortschritte der Physik."—In the election which then followed, Prof. Kundt, the new Director of the Physical Institute, was chosen as first Vice-President in the place of the late Prof. Kirchhoff.—Dr. Koenig spoke on the instantaneous photographs made by Ottomar Anschütz, of Lissa, accompanied by demonstrations and examples of the photographs. Anschütz began taking instantaneous photographs in 1882, operating at first upon bodies of troops during the manœuvres. Later on, at the instance of the Minister of War, he photographed horses and riders moving at every sort of pace. In addition, up to 1885, he busied himself with photographing many animals in the different and frequently very bizarre positions in which they place themselves during their movements. Some of the most interesting photographs taken at this time are those of storks. From 1885 onwards he has been taking serial-photographs of men and animals in motion, obtaining pictures of the consecutive stages of each movement. From these serial-photographs it is possible to draw many scientific deductions, by following the course of the centre of gravity of the object in the successive pictures of horses and men when running and jumping. A complete knowledge of the mechanics of motion can, however, only be arrived at from these series of photographs when the interval of time between each consecutive member of the series is equal and extremely small, a result which Anschütz has nearly obtained. Latterly he has taken pictures of large masses in motion, such as processions, &c. The numerous photographs which the speaker exhibited and briefly explained, testified completely to the technical excellence at which Anschütz has already arrived. The apparatus used for instantaneous photography was exhibited at the same time.

Physiological Society, May 11.—Prof. du Bois-Reymond, President, in the chair.—Dr. Koenig spoke on his measurement of the intensities of light in the spectrum. The method employed was as follows. A circular field of vision was divided into two halves, of which one was illuminated with some colour of the spectrum of fixed intensity, usually with red; the colour to be compared with this was then applied to the other half, and made to vary until it produced the sensation of a light-intensity equal to that of the red. The first measurements were made on Dr. Broddahn, whose eyes are dichromatic (green colour-blind).

By taking the mean of the separate determinations for different parts of the prismatic spectrum, Dr. Koenig had constructed a curve for the light-intensity of all the colours of the spectrum; there was a difference of at most 2 per cent. between the values of the separate measurements and the mean. The speaker then made similar measurements with his own normal trichromatic eyes; in this case he obtained a greater difference between the value of the separate determinations and the mean (up to 5 per cent.) but the curve of light-intensity for the whole range of the spectrum was found to be identical with that obtained from Dr. Broddahn. By reducing the prismatic spectrum used in these experiments to one produced by diffraction, he was able to calculate the curve of light-intensity for a normal spectrum. Comparing this curve with those which he had obtained, in conjunction with Dr. Dieterici, for the sensations of the three primary colours, red, green, and blue (as determined for each point in a normal spectrum), he found that the curve of light-intensity of the spectrum was identical with that for the sensation of red. From this it must be concluded that the sensation of luminous intensity for each separate light is simply dependent on the amount of red contained in it, or, to state this more accurately, the brightness of each kind of light is determined by the extent to which it stimulates the red-perceiving fibres of the retina. Dr. Koenig had some time ago given expression to the conjecture that in the dichromatic eye it is not the fibres for the perception of the third colour which are wanting (the red-perceiving for red colour-blindness and green-perceiving for green), but that they are, so to say, differently tuned; tuned down in those who are colour-blind to green, so that they can only perceive the sensation due to light as red, tuned up to a higher pitch in those who are red colour-blind, so that when they are stimulated by rays of greater wave-length they only perceive green. It is now possible to verify the above conjecture experimentally as follows. The measurements of luminous intensities throughout the spectrum were made upon the eye of another person who was colour-blind, and this time on one who was red colour-blind; in this case the curve obtained was identical with that of the sensation of green. The phenomena observed by Dove, that the relative luminous intensities of red and blue vary according to the intensity of the illumination, were verified by Dr. Koenig, but only up to a certain limit; beyond this limit, the *relative* luminosities of these two colours underwent no further alteration in the brightness of the illumination.—Prof. Gad discussed Prof. Fick's views on blood-pressure in the capillaries, which the latter believed he had placed on an experimental basis by means of an artificial vascular scheme; according to this the pressure in the capillaries could not be much less than in the arteries, and only sinks appreciably as the capillaries are passing over into the veins. Prof. Gad showed that the conditions existing in the above scheme cannot be applied to the blood-capillaries; he further pointed out that the requisite data for calculating the true blood-pressure in the capillaries can be obtained from a theoretical consideration of the rate of flow in, and sectional area of, these vessels, and from this the pressure would appear to be about half of that which exists in the aorta. A true basis for any theory of capillary blood-pressure can only be obtained from such experimental investigation as admits of being applied to various parts of the purely theoretical consideration.

Stockholm.

Royal Academy of Sciences, April 11.—Prof. W. C. Williamson, of Manchester, was elected a foreign member of the Academy.—Critical remarks on the researches of Foeppl on the electrical conductibility of the vacuum, by Prof. Edlund.—A theory of isohydric solutions, by Dr. Arrhenius.—Remarks on the fossils of the Cretaceous formation of Sweden, by Prof. B. Lundgren.

May 9.—On *Triglaps pingelii*, an Arctic fish, found for the first time off the shores of Sweden, and on some specimens of *Syrrhaptes paradoxus* lately shot in Sweden, by Prof. F. A. Smitt.—The whale of Swedenborg (*Balæna swedenborgii*, Liljeborg) found in the diluvial strata of Sweden, described by Dr. Carl Aurivillius.—On the anazotic, stored up nutriments of the Gramineæ, by Dr. C. J. Johanson.—A generalization of the researches of Laplace on the libration in the orbits of the planets, by Dr. K. Bohlin.—On the points of approximation in the theory of perturbation, by the same.—Some extracts from the report of the French scientific expedition to Spitzbergen and other places in the years 1838, 1839, and 1840, by C. B. Lilliehöök, R.N.—Contributions to the theory of the undulatory movement in a gaseous medium (conclusion), by Dr. A. W. Bäcklund.—Derivates of the δ-amido-naphthaline-sulpho-acid, by Prof. P. T. Cleve.—Derivates of the γ-amido-naphthaline-sulpho-acid, by the same.—On naphthol acids, by Dr. Å. G. Ekstrand.—On abnormal forms of the first abdominal appendices of some female cray-fishes, by Dr. D. G. Bergendahl.—On two new Lamellibranchiates from the Arctic post-glacial beds of Scania, by Herr G. Clessin, of Ochsenfurth, Bavaria.

Amsterdam.

Royal Academy of Sciences, April 27.—Mr. J. A. C. Oudemans spoke of Airy's double-image micrometer, and stated the result of his efforts to discover the conditions to which this apparatus must be made to conform, in order that the value of one screw-turn may be independent of the adjustment of the eye. He had found that the distance from the first to the second lens must be equal to the focal length of the first lens—a condition already fulfilled in the micrometer for another purpose.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

British Petrography: J. J. Harris Teall (Dulau).—A Manual of Orchidaceous Plants, Part 3 (Veitch).—Longmans' Commercial Mathematics (Longmans).—A Wanderer's Notes, 2 vols.: W. Beatty-Kingston (Chapman and Hall).—Principles of Agricultural Practice: J. Wrightson (Chapman and Hall).—Discromatopsia, Enrico dal Pozzo di Mombello (Scariglia, Foligno).—Soaps and Candles: J. Cameron (Churchill).—Die Regenverhältnisse der Iberischen Halbinrel: G. Hellmann (Pormetter, Berlin).—Proceedings of the Geologists' Association, February (Stanford).

THURSDAY, JUNE 7, 1888.

TECHNICAL EDUCATION.

WE are glad to see that the Government Bill for the Promotion of Technical Instruction (which we print elsewhere) is down for second reading as first order of the day on June 14. The objects effected by this Bill are substantially the same as those of the Government Bill of last year, and of that already introduced by Sir Henry Roscoe and other friends of education, this year, on behalf of the National Association for the Promotion of Technical Education. That is to say, it is an enabling Bill, giving powers to localities, if they think fit, to apply local rates to the purpose of promoting technical instruction.

In Clause 6, "technical instruction" is defined to mean "instruction in the principles of science and art applicable to industries, and in the application of special branches of science and art to specific industries or employments." It does not include teaching the practice of any trade, or industry, or employment; but, subject to this reservation, it includes "instruction in the branches of science and art with respect to which grants are for the time being made by the Department of Science and Art, and any other form of instruction which may for the time being be sanctioned by that Department by a minute laid before Parliament, and made on the representation of a School Board or local authority that such a form of instruction is required by the circumstances of its district." This definition appears good, so far as it goes, but in our opinion it does not go far enough, for it does not specifically include, as Sir Henry Roscoe's Bill does, the commercial subjects and modern languages. This, however, may easily be amended by a slight alteration of the wording of Clause 6, which should read: "Technical instruction means instruction in subjects applicable to industry and commerce, and in the application of special branches of science and art to specific industries and employment." It is, however, to be noticed that Clause 5 suggests the possibility of Imperial grants in aid of instruction in technical subjects in the words, "Every minute of the Department of Science and Art with respect to the condition on which grants may be made for technical instruction shall be laid on the table of both Houses of Parliament." What the precise nature and amount of such grants may be is not stated, and we shall await with interest the explanation of the Government on this essential point.

In any case, however, it will be necessary that such grants should be accompanied by inspection under Imperial authority, but this does not necessarily form part of the Bill, which, after all, is one simply for giving rating power, and only contains one compulsory clause, viz. that in which School Boards availing themselves of the provisions are required to grant similar powers to voluntary schools in their districts claiming such powers, up, be it always understood, to the limit of one penny in the pound.

There are many points of difference between this Government Bill and that of last year. In the first place, the clause giving powers, granted by the last Bill, to fifty ratepayers to demand a poll is very wisely omitted from this Bill. In the second place, under the Bill of last year the powers of promoting technical instruction could only be exercised by School Boards or by Town Councils where School Boards do not exist. No provision was made for districts in which neither exist. Under the present Bill, where a School Board does not exist, the powers may be exercised by any local authority which can carry out the Public Libraries Acts, and this gives, of course, a much wider sphere of action than the former Bill. But, more than this, the present Bill gives power to Town Councils and other local authorities to grant aid from the rates (even where a School Board exists) to supply higher technical instruction, whereas under the former Bill technical instruction both of an elementary and of a higher character was in the hands of one authority, viz. that of the School Board. Another new point is that the annual rate in aid for technical instruction is limited to one penny in the pound in the case of that levied by the School Board, and at twopence in the pound where the powers given under the Public Libraries Acts are exercised concurrently. In the Bill introduced on behalf of the National Association no such limit is named. Possibly, in view of Parliamentary objections, some limitation is advisable, although very serious objections may be raised to this proposal. Admission to technical schools and classes, may, under Sir Henry Roscoe's Bill, be granted to all comers who pay the required fees; powers being, however, given to Boards and local authorities to institute an entrance examination in reading, writing, and arithmetic, should they think fit. The Government adhere to their former proposal to restrict all attendance in these schools and classes (with the exception of those in which manual instruction alone is given) to such pupils as shall have passed an examination equivalent to that of the Sixth Standard. The exception made this year in favour of manual instruction is a step in the right direction. We should have preferred perfect freedom of admission in the Technical, as is now the case in the Science and Art Classes of the Department, or at least to leave it to the locality to determine whether any such entrance examination is advisable or not.

No powers are granted in the Government Bill respecting payment of fees to deserving students or for the establishment of scholarships, as in Sir H. Roscoe's Bill. These seem to be minor defects, which can be easily remedied. A more important point, and one concerning which not only much discussion in the House of Commons may be expected, but upon which the success or failure of the Bill will probably depend, is the much-vexed question of whether, and, if so, under what conditions, any aid from local rates can be given for the special purposes of technical instruction to public elementary schools not under control of a School Board, *i.e.* to voluntary or denominational schools. Here the difference of opinion between the two great political parties is very marked. One party will not on any consideration sanction payment from the rates unless the spending of this is placed under the definite control of the ratepayers; the other will not permit the Board schools to reap a distinct advantage which is withheld from those carried on by voluntary enterprise. The Bill of the Association summarily cuts the Gordian knot by specifically excluding voluntary schools from participation in income derived from the rates; naturally, therefore, denying to any higher institution of a distinctly denominational type similar assistance. Sir Hart Dyke's Bill, on the other hand, having in its first clause declared that "Any School Board in England may from time to time supply or aid the supply of such manual or technical instruction, or both, as may be required for supplementing the instruction given in any public elementary school in its district, whether under its own management or not," goes still further in its second clause, and makes distinct provision as to the equality of treatment between Board schools and voluntary schools such that, if the Board aids its own schools, "it shall, on the request of the managers of any other public elementary school in its district fulfilling like conditions as to the supply of manual or technical instruction in that school, aid the supply of such instruction in that school in like manner as it aids such supply in the school or schools under its own management, subject to such terms as may be agreed on or determined in pursuance of this Act." Moreover, if the managers object to these terms, the Department of Science and Art shall act as umpire. The support or opposition to this Bill by those who object to payment from the rates without representation, and therefore the probable success or defeat of the measure, will, we venture to think, much depend upon the exact meaning which the Government attaches to these "terms of agreement." If the expression may be taken to mean that the School Board shall have some direct representation by its members on the governing body of the voluntary schools to whom that Board makes grants, *quâ* the technical instruction given in such schools, some of the opposition may possibly be removed. But this should be distinctly expressed; indeed, it would be better to make such an arrangement imperative. If this meaning is not to be attached to these words, we fear that the Bill will lose the support of very many ardent educationalists in the House.

Another provision which we do not find in the Government measure is the one contained in the third clause of the Association Bill, and also in the fourth clause of the Government Bill of last year, in which School Boards may join together to contribute towards the promotion of technical instruction, power being already possessed for this purpose by local authorities under the Public Libraries Acts. This power, in the case of small or sparsely-populated districts, is especially important, with a view to the foundation of higher elementary technical schools, which from their nature do not need to be very numerous, and which the School Boards of many of the single areas of the kind included in the Bill would be quite unable to create or maintain.

The above by no means exhausts the points which may be brought up for discussion on this Bill. It will, however, serve to show the general scope of the Bill, which, unless greatly modified, cannot, we fear, be considered a satisfactory one.

OLD BABYLONIAN AND CHINESE CHARACTERS.

The Old Babylonian Characters and their Chinese Derivates. By Terrien de Lacouperie. (London: Nutt, and Trübner and Co., 1888.)

PROF. TERRIEN DE LACOUPERIE has long been known as the advocate of a theory which would bring the ancestors of the Chinese from Western Asia, and see in the characters they employed derivatives from the cuneiform symbols once in use in Babylonia. The proofs of his theory have been gradually placed before the learned world. In two articles published in the Journal of the Royal Asiatic Society he has endeavoured to trace the history of the Yh-King, the oldest and most mysterious of Chinese books, and to show that its earliest portions contain lists of characters and their meanings, ancient poems and similar fragments of antiquity, misunderstood and misinterpreted by successive generations of commentators. Elsewhere he has given us for the first time a rational account of the vicissitudes undergone by the Chinese system of writing, based upon the statements of the Chinese writers themselves. Lately he has communicated to the Philological Society an interesting and exhaustive description of the languages spoken in China before the arrival of the "Bak" tribes or Chinese proper, as well as of the modern dialects which are descended from them. Now we have the last instalment of his proofs in the shape of a comparison between the primitive forms of the Chinese characters and the pictorial forms out of which the cuneiform script subsequently developed. Prof. de Lacouperie claims to have proved in a typical number of instances that the correspondence is exact, or fairly so, as regards form, signification, and phonetic value; and that consequently an early connection between Chinese and Babylonian must be assumed. Since the Babylonian forms can be shown to presuppose those of China, we must bring the Chinese from the West, and not conversely the Babylonians from the East.

I am not a Sinologist, and therefore can pronounce no opinion on the Sinological side of the argument. Chinese scholars must determine how far Prof. de Lacouperie's restoration of the primitive forms and values of the Chinese signs is correct. Assuming it to be so, the resemblance between many of them and the corresponding characters of Accadian Chaldæa is certainly surprising.

On the Babylonian side, Prof. de Lacouperie has been at great pains to secure accuracy, and has left but little to criticize. *Zik*, however, it may be observed, is not a value of the Babylonian ideograph of "ship," but goes back to an erroneous conjecture of Dr. Hincks; and the original meaning of the character which has the value of *pa* was "the leaf" or "leafy branch" of a tree.

The Babylonians seem never to have forgotten that the cuneiform characters they used had originated in pictures. Indeed, their scribes long claimed the privilege of adding to them, the result being that hieroglyphic forms took their place in the texts by the side of forms that had long degenerated into a cuneatic shape. The original hieroglyphics had been the invention of the so-called Accadians, the early population of Chaldæa, who spoke agglutinative dialects, and were eventually superseded by the Semites.

The Semites received the hieroglyphics from their inventors after they had already assumed a cuneatic form, and added still further to the heritage. When the Semitic king Sargon I. was reigning in Babylonia in B.C. 3800, the scribes at his court were still occupied in devising new forms of characters, and in increasing the number of phonetic values the student was required to learn. This is the cause of the fact pointed out by Prof. de Lacouperie, that, whereas most of the cuneiform characters have to be turned on their sides in order to be restored to their primitive position (Chaldæan writing having once been traced in vertical columns), there are other characters which have never been thus displaced. As time went on, the forms of the characters became more and more distorted; the number of persons in Babylonia who could read and write was very large, and while the general form of script varied from age to age, the individual in each age was distinguished by a peculiar form of handwriting as much as is the individual of to-day. An official scrip never prevailed in Babylonia as it did in Assyria, where education was practically confined to the class of scribes; and while, therefore, the Assyrian student has little need of learning more than one form of writing as long as he confines himself to the monuments of Assyria, he is bewildered by the number of cursive hands which the documents of Babylonia oblige him to decipher.

The oldest Babylonian monuments yet known are those discovered by the French Consul M. de Sarzec at Telloh in Southern Babylonia. They are earlier than the epoch of Sargon I., and belong to the pre-Semitic era. The inscriptions engraved upon them still preserve in some measure the old vertical arrangement of the characters, and in some few cases the characters themselves have a pictorial form. But more generally they have already become cuneatic, and not unfrequently have departed so widely from their primitive appearance as to make it impossible even to guess what they were primarily intended to represent. If this were the case in the fourth millennium before our era, we may have some idea of the vast antiquity to which the beginnings of Babylonian writing must reach back.

In other instances, though the transformation of the character is not so complete, it is difficult to determine with certainty the object originally portrayed. Some of Prof. de Lacouperie's examples are in this plight, and as regards at least two of them—those pronounced *da* and *du* or *tur*—I prefer the explanations suggested by Mr. Pinches and Mr. Bertin to those suggested by himself. In fact, in the first case he has misinterpreted, like the earlier Assyriologists, the Assyrian explanation of the ideograph *nasu sa nisi;* which signifies, not "the summit of man," but "the lifting up of a man." It is consequently natural to regard it as representing the uplifted arm.

Prof. de Lacouperie rejects the theory which saw in the mountains of Elam the birth-place of Babylonian writing. Whatever, however, may be the value of the arguments urged by the advocates of this theory, the arguments brought against it by Prof. de Lacouperie do not appear to me to be cogent. Certainly it is not my experience that the coast of a flat country like Chaldæa "always looks mountainous" to the seafarer; while the Accadian word *a* (misprinted *ai*) signifies "father," not because of the ideographic meaning of the character which represented it, but because the Accadian *ada*, "father," became in pronunciation, through phonetic decay, first *ad*, and then *a*. The symbol of "country" attached to the ideographs of "man" or "servant," "handmaid" and "wild ox," need not have been introduced before the Accadians had long been settled in the Babylonian plain, and it is not quite correct to say that "while [Babylonian writing] possesses primitive symbols for 'boat' and for 'wind,' represented by an inflated sail, there are none for 'river.'" Both "ship" and "river" are alike denoted by a double ideograph.

The question, however, whether the cuneiform system of writing originated in "the mountains of the East," as the Babylonians called them, or in the islands of the Persian Gulf, does not affect Prof. de Lacouperie's main contention. If this can be established, a new and important chapter will be opened in the history of the ancient East, and the mystery which has so long enveloped the origin of the Celestial Empire will be cleared away. I must leave it to the Sinologists to determine whether, on the Chinese side, Prof. de Lacouperie's conclusions are sustainable; on the Babylonian side, he has nothing to fear from Assyrian scholars.

A. H. SAYCE.

DR. EIMER ON THE ORIGIN OF SPECIES.

Die Entstehung der Arten auf Grund von Vererben erworbener Eigenschaften nach den Gesetzen organischen Wachsens. Von Dr. G. H. Theodor Eimer, Professor der Zoologie und vergleichenden Anatomie zu Tübingen. (Jena: Gustaf Fischer, 1888.)

IT is a little curious that, although Darwin was so much more an experimenter than an anatomist, the immediate stimulus of his work was to anatomy, and not to experiment. There is, however, ample evidence that morphology is beginning to advance on the lines prophesied for it at the end of the "Origin of Species," and that morphologists are to enter the "almost untrodden field of inquiry on the causes and laws of variation, on correlation, on the effects of use and disuse, on the direct action of external conditions."

Dr. Eimer's book is written from the stand-point of one who believes that there is more to be made out of the study of the influence of the environment on a single set of organisms than of the anatomy and microscopy of many organisms. It is an abundant storehouse of facts, old and new, about the influence of the physical environment. Many curious problems are dealt with, and the infinite fertility of the field of investigation is shown. But the book claims to be far more than this: it claims to supply a new theory of the organic world—a theory in which natural selection plays only a casual and incidental part.

Dr. Eimer starts from the premiss that natural selection is insufficient to account for the evolution of the organic world because it is essentially the rule of chance. One had thought that this misconception had, even in the controversy of the ignorant, long ago died of inanition. Not only is the whole tenour of Darwin's book opposed to such a conception, but Darwin has specifically guarded against it. For him and for his theory "chance" is but a convenient way of denominating processes of whose details, from their complexity or from their intricacy, we are ignorant.

From his study of the life-conditions of some lizards, Dr. Eimer has reached the conclusion that at any given time variations occur only in a few definite directions. These directions depend on inner constitutional causes. The variations are produced by the direct action of the environment, are always transmitted, and when accumulated, become the inner constitutional cause determining the direction in which the organism will respond to new stimuli. In old males which have been subjected for a longer time than other forms to the environment there is a tendency to the appearance of new characters. These show the direction in which species-variation is going to take place. Not only does the ontogeny repeat the phylogeny in a condensed form, but the later stages of the ontogeny are prophetic of the new phylogeny. Variation, so directed and limited, assimilation causing growth, and reproduction or discontinuous growth, are the chief laws of organic growth.

Suppose a primitive undifferentiated plasma capable of responding to stimuli of heat, light, moisture, &c. In response to the action of the environment ever slightly varied in such details, various conditions would "crystallize out" of the plasma, just as from a homogeneous inorganic mass crystals form in varied groups. As the organic world continued to grow, this original differentiation would increase. With increase of complexity due to the storage in each generation of the complete effect of the environment on each stage of the phylogeny, the different directions in which forms were developing would become more different. Each new character appearing would through correlation influence the whole organism. Allow a little to natural selection and a little to the results of sexual mingling, and the varied species, orders, and classes into which the organic world can now be divided appear as the inevitable result of its mode of growth. There is no need to search for intermediate forms: they may never have existed. As the branching of a tree is the natural consequence of its mode of growth, so is separation and isolation inevitable in the whole organic world.

The two crucial points in Dr. Eimer's theory are his view of the action of the environment and his extreme Lamarckian acceptance of the transmission of acquired characters. Probably he is correct in his supposition that the extent of the direct action of the environment has as yet been unappreciated. Many characters hitherto unexplained may come to be referred to direct action, and experiment only can determine its scope. But it is no explanation of the presence of chlorophyll to refer it with the author to the continued action of sunlight upon protoplasm. And still less is it an explanation of the difference between queen and worker bee to refer it to the difference in their food. But indeed in this latter case the refutation of the author is easy. The neuter is not a different kind of bee produced by a different kind of food. It is merely an arrested queen—a queen that has not become something else on account of a different diet, but a queen that is not quite a queen because it has not had enough to eat. That this is the true state of the case is apparent from the less specialized colonies of wasps. There the queen in spring lays female eggs, and has herself to forage for the whole brood. As a result the young do not get enough to eat, and the development of their sexual organs is arrested. They in turn help to feed the next brood, the individuals of which reach a further state of development. As the summer wears on, the ever-increasing band of workers bring in an increasing supply of food, till finally a condition is reached when there is enough food to make perfect females of a whole brood. Clearly the bee colony, with its sharper distinction between neuter and queen, is merely a specialization of this condition. It is but a verbal explanation of the difference between queen and neuter to refer it to the direct action of food upon the organism. Moreover, to explain the condition of things even in the wasp colony, natural selection is necessary. Obviously, insufficient food would arrest general development as well as sexual development, and natural selection acting on variations naturally arising had to select those whose genitalia suffered most with least detriment to general powers. From the many interesting cases adduced by the author, this one has been selected because it is fairly typical of the slight grounds on which he refers important characters to the direct action of the physical environment.

As for the inheritance of acquired characters, it may be said at once that Dr. Eimer has added nothing of importance to the controversy. He certainly has adduced a few isolated cases that seem to be explained best on this theory; and were the inheritance of acquired characters merely of incidental value to his argument, his easy acceptance of the traditional view might avoid criticism. But when it is said that the direct action of the environment, together with inner constitutional causes, produces varieties and species, and that these inner constitutional causes that determine the direction of variation are merely a summation of direct action, a summation effected by inheritance, we perceive at once that a new and all-important *rôle* is assigned to heredity. There is no attempt to meet the serious theoretical difficulties involved in every conception of the mechanism of the inheritance of acquired characters: there is no adequate attempt to establish the fact. Were it possible and were it true, undoubtedly it would be, as Dr. Eimer in elaborate and learned detail has shown, of immense importance. But to prove its possibility or truth Dr. Eimer has done little or nothing.

Dr. Eimer appears to have mistaken a generalized expression of the process of evolution for an explanation of it. Natural selection acts at a time only on the one or two characters which the environment temporarily elevates into criteria of existence. But, as these change, there are changed with them a vast multitude of minor characters—in a word, there results what the author happily calls "kaleidoscopic variation." These changes can be referred only indirectly to selection, though they may play no inconsiderable part in determining the appearance of the organism. With all these variations are correlated variations in the results produced by the direct physical action of the environment.

Dr. Eimer has concentrated his attention on these secondary and certainly neglected changes, and his theory is a statement of their course. But he has brought forward no motive power to take the place of natural selection in determining the ruling changes; and therefore his generalized statement, even when raised into a law and dignified with a name, is not an explanation of the phenomena. Darwin has convinced men of evolution where Lamarck failed and where certainly Dr. Eimer would fail, not because he discovered any law, but because he discovered an intelligible mechanism, an obvious sequence of cause and effect, which could, and probably did, act. P. C. M.

OUR BOOK SHELF.

The Birds of Dorsetshire: A Contribution to the Natural History of the County. By J. C. Mansel-Pleydell, B.A., F.L.S., &c. 8vo. pp. i–xvi., 1–179. (London and Dorchester: R. H. Porter, 1888.)

Notes on the Birds of Herefordshire, contributed by Members of the Woolhope Club. Collected and Arranged by the late Henry Graves Bull, M.D., &c. pp. i–xxxii., 1–274. (London and Hereford: Jakeman and Carver, 1888.)

COUNTY lists of birds are still the order of the day. First we have Mr. Mansel-Pleydell's book on the Ornithology of Dorsetshire, a very neat little volume, compiled evidently with the greatest care. The author's long acquaintance with the country and his well-known love of natural history have rendered him the most competent authority on the subject, and he has been aided by many well-known naturalists in supplying him with instances of the capture of rare birds, so that the list is a very complete one. The inevitable Great Black Woodpecker (*Picus martius*) of course appears, on Pulteney's authority, but no recent specimen is extant, nor is likely to be. The Pied-billed Grebe (*Podilymbus podiceps*), which was first recorded by ourselves as a British bird, is placed between brackets, and considered to be "extremely doubtful" by the author. All we can say is that we should not have been godfather to the specimen, to add one more doubtful species to the already overburdened British list, unless we had felt tolerably certain of its authenticity, while the fact of the specimen being immature renders its occurrence as a chance wanderer much *more* probable than if it had been an adult bird in breeding-plumage. The bird has ten times more claim to a place amongst our stragglers than such species as *Picus medius*, *Pycnonotus barbatus*, and dozens of others. A most interesting history is given of the celebrated swannery at Abbotsbury, with a photographic plate, in which the birds are well depicted, but the keeper's face lacks expression! Some pretty woodcuts by Mr. Lodge are interspersed in the text. The author informs us that *Puffinus obscurus* (p. 113) should be *P. griseus*.

Dr. Bull's "Birds of Herefordshire" is one of the most useful of the county lists; for it contains a complete list of British birds, with special notes on the Herefordshire species. A great deal of care has evidently been taken over this book, which is rendered more interesting by the poetical researches of the author. Mr. Phil. Robinson, when he issues a new edition of his "Poets' Birds" will certainly have to consult this work of Dr. Bull, which contains many quotations we have not seen elsewhere.

R. BOWDLER SHARPE.

Geology for All. By J. Logan Lobley, F.G.S., &c. (London: Roper and Drowley, 1888).

THE object of this little book is to give an account of the important facts and deductions in geology, without "unnecessary scientific terminology." That there is room for such a work will not be questioned, and doubtless many who have paid no heed to the subject would begin to study it if only their lessons were made easy and attractive. This was accomplished in old times by Hugh Miller, and more recently by Canon Kingsley in his charming "Town Geology"; and Mr. Lobley, in his enthusiastic preface, raises the hope that he will follow a similar course, and provide "all intelligent readers" with a simple record of the earth's history. In this respect, however, we are disappointed. The work is a condensed account of the leading geological facts and deductions, arranged much after the fashion of an ordinary text-book. Of its general accuracy and clearness we can speak with confidence; and indeed, through his long connection with the Geologists' Association, the author has had ample opportunities of qualifying himself for his task. The work, however, is more adapted for the young student who wishes to pursue the subject, than for the general reader. We fear the patience of the latter will be tried when he reads the explanations—and not always happy explanations—of outcrops, anticlinals, unconformities, and outliers, for there are no diagrams to give pictorial aid. Nor is the chapter on the composition of rocks likely to prove more readable; for surely the accounts of the physical characters of minerals, and the chemical formulæ, introduce "unnecessary scientific terminology." Again, when we read of the acidic and basic rocks, of the seismic focus and the meizoseismic curve, of the "homocircle (*sic*) or equal-lobed tailed fishes," and of those that present a "heterocircle-tailed character," we feel that the author has not sufficiently carried out his good intentions. In the chapter on metamorphic rocks a popular account might have been given of recent researches in the Highlands, and then perhaps the author would not have remarked that "rarely a reversed-fault is seen." H. B. W.

Sound, Light, and Heat. By Thomas Dunman.
Electricity and Magnetism. By the same Author. (London: Ward, Lock, and Co., 1888.)

THESE two books are revised reprints of the articles on the subjects which have already appeared in Messrs. Ward, Lock, and Co.'s well known "Universal Instructor." They have been published in their present form for the convenience of students. The work of revision and expansion has been undertaken by Mr. Chapman Jones, the death of the original author having rendered it necessary for other hands to perform this part of the work.

As might be expected, the books are of a popular character, but their value to students of elementary physics does not in the least suffer on this account. The almost entire absence of mathematical statements makes them suitable for the most elementary students.

The method of treatment is that of the orthodox text-book, and there is very little that calls for special remark. They differ mainly from other elementary text-books inasmuch as they are brought quite up to date, especially in electrical matters. The 300 diagrams which are distributed throughout the text, though not of a high order of excellence, will do much towards enlightening the minds of those who read the books.

Though not designed to suit the syllabus of any examining body, they are well adapted for students preparing for the Science and Art Department examinations.

Sea-side and Way-side. By Julia McNair Wright. (Boston: D. C. Heath and Co., 1888.)

THIS little volume is the first of a series of "Nature Readers," intended for the use of beginners in reading. As a rule, the authors of reading-books take little trouble to excite the interest of children. Their object is to bring together a number of simple sentences, and they seem to be indifferent whether the sentences express sense or nonsense. In the present series an attempt will be made to convey, through reading-lessons, some of the more attractive elementary facts of science; and, if we may judge from the degree of success attained in "Sea-side and Way-side," the volumes are likely to be cordially welcomed in many primary schools in England as well as in the United States. The author has taken, as the subjects of her lessons, crabs, wasps, bees, spiders, and shell-fish; and she has contrived to put into the simplest and most direct language a great deal of really useful and entertaining information. Almost all children find something to interest them in what they are told about the habits of animals, and it is not improbable that these bright and pleasant lessons will implant in a good many young minds the seeds of an enduring love of natural history.

Reminiscences of Foreign Travel. By Robert Crawford. (London: Longmans, Green, and Co., 1888).

MR. CRAWFORD is already favourably known as the author of "Across the Pampas and the Andes." The present volume will maintain his reputation as a traveller who knows how to observe what is most significant in the countries he visits, and who possesses the faculty of reproducing his impressions in a lively and attractive narrative. His reminiscences relate to Canada, Austria, Germany, Sardinia, Egypt, Algeria, and various other lands; and in every chapter he records something that most readers will find fresh and interesting. The most instructive sections of the book are, upon the whole, those relating to Canada and Algeria.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dr. Giglioli and Lepidosiren.

DR. GIGLIOLI asserts, in his interesting letter published in the last issue of NATURE (p. 102), that the Lepidosiren whose capture he records is "the fifth specimen known." Reference to his earlier remarks (NATURE, vol. xxxv. p. 343), concerning that which he regards as "the fourth known" specimen, shows that while he has acknowledged the examples of Natterer and Castlenau, he has apparently overlooked that of Bibron and H. Milne-Edwards, recorded in 1840. Readers of NATURE interested in this wonderful creature, now apparently verging on extinction, will find a *résumé* of all that is topographically important concerning the last-named and the three previously recorded specimens in the *Zoolog. Jahrb.* for 1887 (pp. 575 to 583). For this welcome communication, to which a full bibliography is appended, we are indebted to Dr. G. Baur, of Yale College Museum, U.S.A. It forms one of the series of historical miscellanea with which he has enriched our recent literature; and, if the conclusions at which he (in common with Brühl) arrives are sound, Dr. Giglioli's "fifth" specimen will be in reality a sixth.

Zoologists in general will unite in congratulating Drs. Rodriguez and Giglioli upon their recent acquisition; and while hoping for a repetition of the same, they will eagerly await the results of the promised "future study." G. B. HOWES.

South Kensington, June 2.

"A Text-book of Biology."

WILL you allow me to point out that the reviewer, in your issue of May 17 (p. 52), apparently misunderstands the object of my "Text-book of Biology"? The work is not meant to supplant lectures, but to aid them, by reducing for the student the wearisome labour of note-taking, and by enabling the teacher to enlarge where necessary, and to treat the subject from other points of view, running meanwhile less risk of addressing an audience of mere scribbling-machines.

The review also implies that a previously published work covers the same ground as the present book. This, however, is not the case, as my book deals with the *Botany* as well as with the Zoology of the course.

I cannot but think that the reviewer is led by his enthusiasm into the common mistake of demanding that the ordinary "pass" man shall follow the same course as the specialist. I suppose that the University of London prescribes at the Intermediate Pass stage a portion, not too small, of Biology, which shall form part of a general course of science adapted to the average student, and to *the time at his disposal;* perhaps your reviewer will kindly explain, less vaguely, what other system he would propose to substitute? J. R. AINSWORTH DAVIS.

Aberystwyth, May 24.

Resistance of Square Bars to Torsion.

THE attention of writers on Applied Mechanics should be called to the error continuously repeated in about thirty editions of the late Prof. Rankine's different works which have appeared during the last thirty years. The error is still reproduced in quite recent works of other writers: Prof. Ewing's article, "Steam-Engine," in the Encyclopædia Britannica; Prof. Unwin's "Elements of Machine Design"; Prof. Alexander's "Elementary Applied Mechanics"; &c.

It is stated that the moment of resistance of a square bar to torsion appears from Saint-Venant's investigations to be—

$$0{\cdot}281\, fh^3,$$

where f = maximum intensity of stress, and h = side of the square. This formula is also quoted at discussions of Institutions of Engineers and accepted without dissent. It is easily seen to be wrong, because the moment of torsion of a round bar of equal area is only

$$0{\cdot}282\, fh^3.$$

The error is reproduced in the text of Prof. Cotterill's "Applied Mechanics," but is corrected in an appendix, where the author says Rankine gives the formula without further explanation. The explanation is that on the old theory the torsional moment of inertia was—

$$I = \frac{h^4}{6},$$

which had to be multiplied by the maximum intensity of stress and divided by the corresponding radial distance—namely, from the centre to the middle of the side, giving the moment of resistance

$$= \frac{fh^3}{3}$$

on the old theory. (Rankine was aware that the maximum stress does not occur at the angles, as in Coulomb's method.)

Now, in Saint-Venant's "Mémoire," the *torsional rigidity* of a square bar is proved to be the fraction

$$0{\cdot}843$$

of the fallacious result of the old theory. Rankine accordingly wrote

$$0{\cdot}843 \times \frac{fh^3}{3} = 0{\cdot}281 fh^3$$

as the true moment of torsion.

But the *torsional rigidity* determines the *amount of twist*, and not the *maximum stress*. A few pages farther on, Saint-Venant gives the correct formula, equivalent to

$$\mathbf{0{\cdot}208}\, fh^3.$$

It seems strange that the talented author of the expressive distinctions *strain* and *stress* should himself have taken the formula for the strain instead of that for the stress. The reason is, that up to that date (Todhunter's "History of Elasticity") the strain and stress were supposed to be proportional to each other.

Abstracts of Saint-Venant's researches are given in Sir William Thomson's article "Elasticity," in the Encyclopædia Britannica, Thomson and Tait's "Natural Philosophy," and Minchin's "Statics." Strange that in all of these the method is given which determines the *strain* to be 0·843 of the old fallacy, while nothing is said about what is of more importance in Applied Mechanics, the maximum *stress*, nor the *moment of resistance to torsion*, as given above.

Perhaps this hint may be attended to in future editions.

T. I. DEWAR.

Engineering Academy, 721 Commercial Road, E.

THE GEOLOGICAL STRUCTURE OF SCANDINAVIA AND THE SCOTTISH HIGHLANDS.

THE obvious connection and analogy between the geological structure of the crystalline rocks of the Highlands of Scotland and those of Scandinavia have long engaged the attention of geologists. Among the northern observers to whose labours we are largely indebted for our knowledge of the Scandinavian regions, Dr. A. E. Törnebohm has proved himself a keen and indefatigable explorer of the Swedish uplands. Many years ago he showed that above clay-slates and limestones, with recognizable Silurian fossils, there lies a great thickness of quartzites, gneisses, and schists, called by him the Seve group. In more recently studying the relations of these rock-masses, he encountered some great difficulties, of which he sent me at the time an account. I could not pretend to solve them, but suggested, as at least a working hypothesis, that the Scandinavian structure might be fundamentally similar to that now recognized as characteristic of the North-West Highlands, where the apparent conformable superposition of a series of schists upon fossiliferous Lower Silurian strata has been produced by great terrestrial displacements, whereby the overlying rocks have been crushed and deformed, until they have assumed a new crystalline structure along the planes of movement, these stupendous changes having occurred at some time subsequent to the Lower Silurian period. I have recently received from Dr. Törnebohm the following letter, which he gives me leave to publish, and which will no doubt be read with interest by those who are aware of the recent progress of research in this subject:—"It will perhaps interest you to learn that your suggestion four years ago regarding the construction of our Scandinavian *fjelds* has turned out to be correct, at least in my opinion. My late researches have little by little driven me to the conclusion that the crystalline schists belonging to what I have called the 'Seve group' have been placed over Silurian strata by an enormous eastward thrust. I admit that I have most reluctantly come to this conclusion, knowing that it implied a horizontal thrust of enormous masses of rock for more than 100 kilometres. Such a stupendous movement of entire mountain-regions is hard to realize; but facts are stubborn things."

It will be observed that Dr. Törnebohm speaks of the movement having been towards the east, whereas in the north-west of Scotland it has been in the opposite direction. In a more recent letter, in reply to one in which I had called his attention to this difference, he says:—"Though in Scotland the great thrusts are westward, in Scandinavia it is quite the reverse. Here the chief movement has been to the east or south-east. In the region of Trondhjem, indeed, there have been lesser movements towards the north-west, but these may have taken place somewhat later. At least I rather suspect this, but am not prepared positively to affirm it." I may remark that in Scotland also there are districts where the thrusts have not come from the normal direction but from the westward. In the Island of Islay, for example, I recently found the limestones and quartzites piled up by sharply-cut thrust-planes which had a general westward inclination at lower angles than the displaced strata. One of the great problems in working out the complicated geology of the Highlands is the determination of the positions and extent of such thrust-planes, and the direction in which the displaced rock-masses have been moved. There can be little doubt that much mutual help in this research will be gained by a co-operation between the field geologists who are engaged in the study of these problems in Scotland and in Scandinavia.

ARCH. GEIKIE.

TIMBER, AND SOME OF ITS DISEASES.[1]

VIII.

THERE is a large and important class of diseases of standing timber which start from the cortex and cambium so obviously that foresters and horticulturists, struck with the external symptoms, almost invariably term them "diseases of the bark"; and since most of them lead to the production of malformations and excrescences, often with outflowing of resinous and other fluids, a sort of rough superficial analogy to certain animal diseases has been supposed, and such terms as "canker," "cancer," and so forth, have been applied to them.

Confining our attention to the most common and typical cases, the following general statements may be made about these diseases. They usually result from imperfect healing of small wounds, the exposed cortex and cambium being attacked by some parasitic or semi-parasitic fungus, as it tries to heal over the wound. The local disturbances in growth kept up by the mycelium

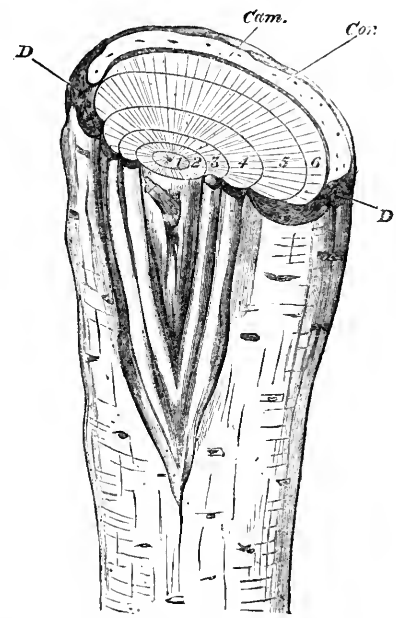

FIG. 28.—Piece of tree stem affected with "canker." The injury commenced after the two inner zones of wood (1 and 2) had been developed: it extended further in successive periods of growth, as shown by the receding zones 3, 4, 5, and 6, until all the cambium and cortex was destroyed except the pieces *D* to *D*. *Cam*, cambium; *Cor*, living cortex; *D D*, dead tissues. At each period of growth the attempt has been made to heal over the wound, as shown by the successively receding lips.

feeding on the contents of the cells of these tissues lead to the irregular growths and hypertrophies referred to; the wounds are kept open and "sore," or even extended, and there is hardly any limit to the possibilities of damage to the timber thus exposed to a multitude of dangers.

In Fig. 28 is represented a portion of a tree stem affected with "canker": the transverse section shows the periods of growth numbered 1 to 6 from within outwards. When the stem was younger, and the cambium had already developed the zones marked 1 and 2, the cortex suffered some injury near the base of the dead twig, below the figure 1. This injury was aggravated by the ravages of fungus-mycelium, which penetrated to the cambium and destroyed it over a small area: in consequence of this, the next periodic zone of wood (marked 3) is of course incomplete over the damaged area, and the cortex and cambium strive to heal over the wound by lip-like callus at the margins. The healing is prevented,

[1] Continued from p. 111.

however, by the mycelium, which is continually extending the area of injury: consequently the next zone of wood (4 in the figure) extends even a shorter distance round the stem, and so on with 5 and 6, the cambium being now restricted to less than half round the stem—*i.e.* from *D* to *D*, and the same with the living cortex. Of course the injured area extends upwards and downwards also, as shown by the lips of the healing tissue. As soon as the injury extends all round, the stem dies—it is, in fact, ringed. It is also interesting to note that the zones 4 and 5 (and the same would be true of 6 when completed) are thicker than they would have been normally: this is partly due to release from pressure, and partly to a concentrated supply of nutritive materials.

Much confusion still exists between the various cases: some of them undoubtedly are due to frost or to the intense heat of direct insolation; these are, as a rule, capable of treatment more or less simple, and can be healed up. Others, again, can only be freed from the irritating agents (which, by the bye, may be insects as well as fungi) by costly and troublesome methods.

I shall only select one case for illustration, as it is typical, and only too well known. As examples of others belonging to the same broad category, I may mention the "canker" of apple-trees, beeches, oaks, hazels, maples, hornbeams, alders, and limes, and many others; and simply pass the remark that whatever the differences in detail in the special cases, the general phenomena and processes of reasoning are the same.

Perhaps no timber disease has caused so much consternation and difference of opinion as the "larch-disease," and even now there is far too little agreement among foresters either as to what they really mean by this term, or as to what causes the malady. The larch, like other timber-trees, is subject to the attacks of various kinds of fungi and insects, in its timber, roots, and leaves; but the well-known larch-disease, which has been spreading itself over Europe during the present century, and which has caused such costly devastation in plantations, is one of the group of cancerous diseases the outward and visible signs of which are manifested in the bark and young wood.

The appearance presented by a diseased larch-stem is shown in Fig. 29. In the earlier stages of the malady the stem shows dead, slightly sunken patches, *a*, of various sizes on the cortex, and the wood beneath is found to cease growing: it is a fact to be noted that the dead base of a dried-up branch is commonly found in the middle of the patch. The diseased cortex is found to stick to the wood below, instead of peeling off easily with a knife. At the margins of the flattened patch, just where the dead cortex joins the normal living parts, there may frequently be seen a number of small cup-like fungus fructifications (Fig. 29, *b*), each of which is white or gray on the outside, and lined with orange-yellow. These are the fruit-bodies of a discomycetous fungus called *Peziza Willkommii* (Htg.), and which has at various times, and by various observers, received at least four other names, which we may neglect.

In the spring or early summer, the leaves of the tree are found to turn yellow and wither on several of the twigs or branches, and a flow of resin is seen at the dead patch of cortex. If the case is a bad one, the whole branch or young tree above the diseased place may die and dry up. At the margins of the patch, the edges of the sounder cortex appear to be raised.

As the disease progresses in succeeding years, the merely flattened dead patch becomes a sunken blistered hole from which resin flows: this sinking in of the destroyed tissues is due to the up-growth of the margins of the patch, and it is noticed that the up-growing margin recedes further and further from the centre of the patch. If this goes on, the patch at length extends all round the stem or branch, and the death of all that lies above is then soon brought about, for, since the young wood and cambium beneath the dead cortex are also destroyed, the general effect is to "ring" the tree.

To understand these symptoms better, it is necessary to examine the diseased patch more closely in its various stages. The microscope shows that the dead and dying cortex, cambium, and young wood in a small patch, contain the mycelium of the fungus which gives rise to the cup-like fructifications—*Peziza Willkommii*—above referred to (Fig. 30); and Hartig has proved that, if the spores of this *Peziza* are introduced into the cortex of a healthy living larch, the mycelium to which they give rise kills the cells of the cortex and cambium, penetrates into the young wood, and causes the development of a patch which everyone would recognize as that of the larch-disease. It is thus shown that the fungus is the immediate cause of the patch in which it is found.

The next fact which has been established is that the fungus can only infect the cortex through some wound or injury—such as a crack or puncture—and cannot penetrate the sound bark, &c. Once inside, however, the mycelium extends upwards, downwards, sideways, and inwards, killing and destroying all the tissues, and so inducing the outflow of resin which is so characteristic of the disease. The much-branched, septate, colourless

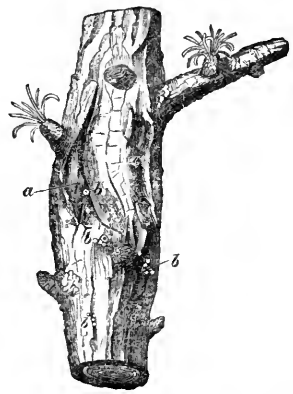

Fig. 29.—Portion of stem of a young larch affected with the larch-disease, as indicated by the dead "cancerous" patch of cracked cortex, *a*: at and near the margins of the patch are the small cup-like fructifications of *Peziza Willkommii* (Htg.), which spring from mycelium in the dead and dying cortex and cambium beneath. (After Hess.)

hyphæ can penetrate even as far as the pith, and the destroyed tissues turn brown and dry up.

After destroying a piece of the tissues in the spring, the growth of the mycelium stops in the summer, the dead cortex dries up and sticks to the wood, and the living cortex at the margins of the patch commence to form a thick layer of cork between its living cells and the diseased area.

It is this cork-formation which gives the appearance of a raised rim around the dead patch. It has long been known that the patches dry up and cease to spread in the dry season. It should be pointed out that it is one of the most general properties of living parenchymatous tissue to form cork-cells at the boundaries of an injury: if a slice is removed from a potato, for instance, the cut surface will be found in a few days with several layers of cork-cells beneath it, and the same occurs at the cut surface of a slip, or a pruned branch,—the "callus" of tissue formed is covered with a layer of cork.

If it is remembered that the cambium and young wood are destroyed beneath the patch, it will be at once clear that in succeeding periods of growth the annual rings of wood will be deficient beneath the patch.

Next year, the cambium in the healthy parts of the stem begins to form another ring; but the fungus mycelium awakens to renewed activity at the same time, and spreads a little further upwards, downwards, and sideways, its hyphæ avoiding the cork-layer and traversing the young wood and cambium below. During this second spring, therefore, a still larger patch of dead tissue—cortex, cambium, and young wood—is formed, and the usual cork-layer describes a larger boundary. Moreover, since the cambium around the, as yet, undiseased parts has added a further annual ring—which of course stops at the boundaries of the diseased patch—the centre of the patch is yet more depressed (cf. Fig. 28).

And so matters go on, year after year, the local injury to the timber increasing, and ultimately seriously affecting, or even bringing to an end, the life of the tree.

At the margins of the diseased patches, as said, the fungus at length sends out its fructifications. These appear at first as very minute cushions of mycelium, from which the cup-like bodies with an orange-coloured lining

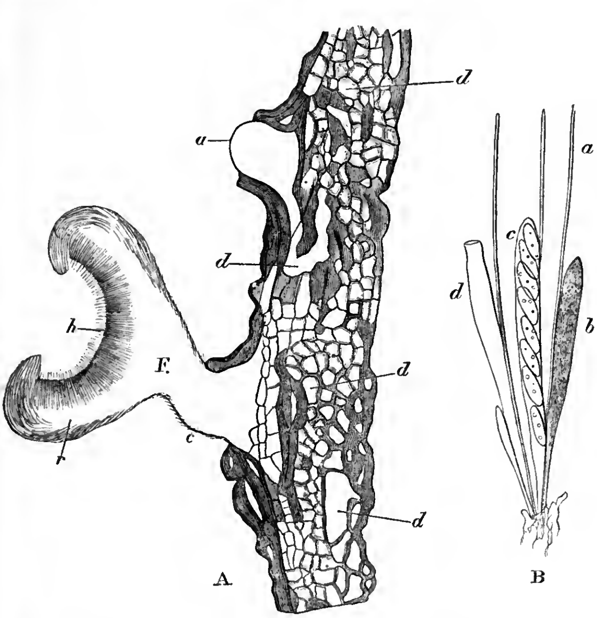

FIG. 30.—A, vertical section (magnified) through the dead cortex of a larch, infected with the mycelium (*d*) of *Peziza Willkommii* (Htg.), which is developing its fructifications (*a* and *E*). The mycelium fills up the gaps in the cortex, *d*, with a white felt-work. *a* is a boss-like cushion of this felt-work bursting forth to become a cup-like fructification; *F*, the mature *Peziza* fructification (in section); *c*, its stalk; *r*, the margins of the cup; *h*, the layer of spore-sacs (*asci*). B, four of the asci from *h*, very highly magnified. *a*, hair-like barren filaments between the asci; *c*, a fully-developed ascus, containing the eight spores; *d*, an ascus emptied of spores (they have escaped through the hole at the apex); *b*, a young ascus in which the spores are not yet formed: to the left below is a small one still younger. (After Hartig and Willkomm.)

arise: the structure of this fructification is best seen from the illustration (Fig. 30, A). The orange-red lining (*h*) is really composed of innumerable minute tubular sacs, each of which is termed an *ascus*, and contains eight small spores: as seen in the figure (Fig. 30, B), these asci stand upright like the pile of velvet lining the cup. They are formed in enormous numbers, and go on ripening and scattering the spores day after day. There are many interesting details connected with the development and structure of these fructifications and spores; but we may pass over these particulars here, the chief point for the moment being that very large numbers of the minute spores are formed, and scattered by the wind, rain, animals, &c. Moreover, as already stated, it has been shown by experiments that the spores will infect the stem of the larch if they are introduced into a wound; but it is important to notice that the fungus cannot penetrate the sound cortex.

It now remains for us to see if, in the natural course of events, infection of the larch can take place to any great extent; for, unless this is the case, we cannot reconcile the above peculiarities of the fungus with the prevalence of the disease.

It must be borne in mind that the larch is an Alpine tree, growing naturally at an elevation of from about 3000 to 6000 feet above sea-level, and even more. In its native heights, both the larch-disease and *Peziza Willkommii* occur associated as we have described them, but the malady does not become epidemic, as it has done in the valleys and plains of Europe.

Several insect-enemies of the larch are known, some of which feed on the buds, and others on the leaves, &c.: it is not impossible that insect-wounds may serve occasionally as points of entry for the fungus.

But attention should be directed to the remark made when describing the symptoms of the disease—namely, that a dead branch often springs from near the centre of the patch. Now it is a well-known fact in the hill-forests of Switzerland, Germany, Austria, &c., that heavy falls of snow often load the branches until they bend down to the ground, and the bark in the upper angle where the branch joins the stem is ruptured; similar cracks are also caused by the bending down of the branches under the weight of water condensed from mists, &c. If a spore alighted near such a place, the rain would wash it into the crevice, and it would germinate in the moisture always apt to accumulate there. This certainly accounts very completely for the situation of the dead branch, which of course would at once suffer from the mycelium. Another way in which such wounds as would give access to the parasite might arise, is from the blows of hailstones on the still young and tender cortex.

But probably the most common source of the crevices or wounds by which the fungus gains an entry is frost; and to understand this we must say a few words as to what is known of the larch at home in its native Alps.

It is well known, since Hartig drew attention to the fact, that in the high regions of the Alps the trees begin to put forth their shoots very late: the larch in the lowlands of Germany and the British Isles often begins to shoot at the end of March or beginning of April, whereas in the mountains it may be devoid of leaves in May. This is because the transition from winter to spring is very sudden on high slopes, whereas in the lowlands and valleys it may be very gradual. The consequence is that in the Alps, when the buds once begin to open they do this rapidly and vigorously, and the tender leaves and shoots are quickly formed and beyond the reach of those late spring frosts which do so much damage in our country: in the lowlands, on the contrary, the leaves slowly develop at a time when late frosts are very apt to recur at night, and they are for several weeks exposed to this danger; and if a sharp frost does come, the chances are that not only will the first output of tender leaves be killed off, but the whole shoot suffers, and frost-wounds are formed in the young cortex.

Another point comes into consideration also. In warm damp valleys the whole tree is apt to be more watery, and it is well known that the soft tissues, like the cortex, suffer more from frost when filled with watery sap, than do harder, drier, more matured ones. It has been shown, according to Sorauer, that dead patches, exactly like those which characterize the larch-disease in its early stages, can be artificially produced by exposing the stem to temperatures below zero, so as to freeze the water in the cells.

Given the above conditions for producing frost-wounds, then, and the presence of spores of *Peziza Willkommii*, there is no difficulty in explaining the well-known phenomena of the larch-disease.

But Hartig has brought to light some other facts of great importance in considering this admittedly complex question. We have already stated that the *Peziza* does occur at the margins of the wounds in the Alps where the larch is native. In these higher regions, however, the air is usually dry during periods of active growth and the young fructifications of the fungus are particularly sensitive to drought; consequently, even when many scattered trees are infected, the cups developed at the edges of the wounds are apt either to dry up altogether, or to produce relatively few spores, and these spores have fewer chances of germinating. In fact, the fungus enjoys at best a sporadic existence, chiefly at the bases of trees where the herbage affords a certain degree of dampness.

When the larch was brought down to the plains and valleys, however, and planted in all directions over large areas, the *Peziza* was also brought with it; but it will be clear from the foregoing discussion that the climatic conditions were now proportionally raised in favour of the fungus, and lowered to the disadvantage of the larch. Plantations in damp valleys, or in the neighbourhood of the sea, or of large lakes, were especially calculated to suffer from frost, and the damp air favoured the propagation of the fungus, and the disease tended to become epidemic. The enormous traffic in larch plants also shows how man too did his share in spreading the epidemic; and in fact the whole story of the larch-disease is of peculiar interest biologically, as illustrating the risks we run every day in trusting to the chapter of accidents to see us safely through any planting undertaking, no matter how great the stake at issue, or how ruthless the interference with those complex biological and physical conditions which always play such an important part in keeping the balance in the struggle for existence between all organisms living together.

Let us now very shortly see what are the chief lessons taught us by the bitter and costly experience which the larch-disease brought to foresters. It is evident that the larch should not be planted at all in low-lying situations exposed to late frosts; and even in more favoured valleys experience points to the advantage of mixing it with other trees: large areas of pure larch are planted at enormous risk in the lowlands.

As to the treatment of trees already diseased, it is possible (when it is worth while) to remove diseased branches from trees of which the trunk and crown are healthy, but it hardly needs mention that such diseased branches must be burnt at once. As regards trees with the stems diseased—in those cases where the patches are large, and much resin is flowing from the wounds, experience points to the advisability of cutting them down. In those cases where the tree is already very large, and the diseased wound but small, it may be expedient to let them alone: theoretically they ought to go, or at any rate the diseased tissues be excised and burnt; but it seems to be proved that such a tree may go on forming timber for many years before the wound will spread far enough to reduce the annual increment below the limits of profit, and we all know the view a practical forester will take of such a case. At the same time, it is the duty of the man of science to point out that even such a tree is a possible source of danger to its neighbours.

H. MARSHALL WARD.

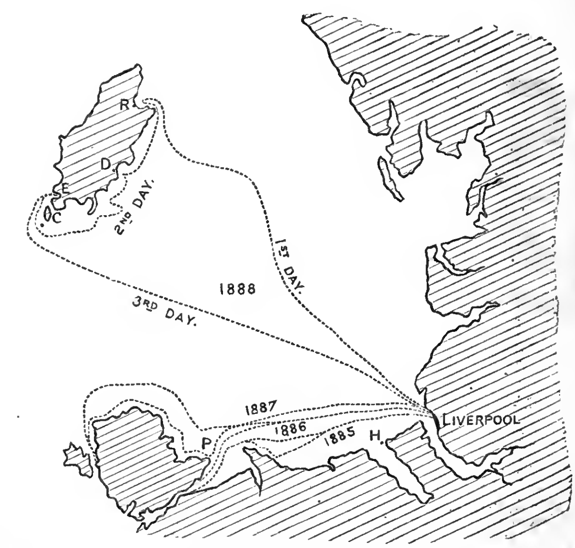
(*To be continued.*)

MARINE BIOLOGY AND THE ELECTRIC LIGHT.

THE Liverpool Salvage Association, with their usual liberality, placed their famous old steamer the *Hyæna* once more at the service of the Liverpool Marine Biology Committee this Whitsuntide, for a three days' dredging expedition. During the three former biological cruises of the *Hyæna* in 1885, 1886, and 1887, the region explored has been the southern part of the L.M.B.C. district, around the coasts of North Wales and Anglesey (see Fig.).

On the present occasion the Committee decided to run a couple of lines of soundings and dredgings between the Mersey and the Isle of Man, and to spend some time dredging round the southern end of that island; the general objects being (1) to get some knowledge of the depths, bottom, and animals, across the eastern half of the Irish Sea, and (2) to investigate the rich fauna living around the "Calf" and south end of the Isle of Man.

About 7 a.m. on Saturday morning, May 19, the *Hyæna* left the Liverpool landing-stage, with a party of nearly twenty biologists on board, and provided with dredges, trawls, tow-nets, sounding-line, deep-sea reversing thermometer, microscopes, and the other necessary instruments, dishes, bottles, and reagents. After the well-known sand-banks round the mouth of the Mersey had been passed, soundings and bottom temperatures were taken occasionally, and several times during the day a stop was made for trawling, dredging, and tow-netting. A fair amount of material, including some interesting larval forms, was obtained, and for the most part preserved for further examination. No greater depth than 23 fathoms



Map of the L.M.B.C. District, showing the course of the *Hyæna* in 1885, 1886, 1887, and 1888. H, Hilbre Island; P, Puffin Island; R, Ramsey: D, Douglas; E, Port Erin; C, the Calf.

was, however, met with; and there was nothing specially noteworthy amongst the animals dredged, so far as could be seen at the time.

It had been intended to anchor for the night in Douglas Bay, but during the dredging and trawling the vessel had drifted so far out of her course that when evening came it was found advisable to run for Ramsey. Here half the party went on shore for the night, the rest staying on board for the electric light experiments which will be described further on.

On the following morning an early start for the south was made, and the rest of the party was picked up at Douglas, and then the work of the day commenced. The *Hyæna* steamed slowly round the east and south coasts of the island to Port Erin, dredging and tow-netting at intervals, with very good results. When a stop was made for collecting, the fullest advantage was taken of it. The sounding-line and deep-sea thermometer were over amidships, and two dredges, a large bottom tow-net and one or more surface tow-nets, were put out astern. The deep tow-net, devised and worked by Mr. W. S. McMillan, was so weighted and buoyed as to work steadily at a distance of a foot or so above the sea-bottom, and it yielded a large amount of material, which was in some cases conspicuously different from the contents of the surface nets, worked by Mr. I. C. Thompson during the same time.

A large area of the sea bottom between Port Soderic and Port St. Mary is apparently covered by masses of *Melobesia calcarea* and the dead valves of *Pectunculus glycimeris*, and incrusting Polyzoa are especially abundant upon both the Nullipore and the shells. Mr. J. Lomas, who has charge of the Polyzoa, informs me that amongst a number of other rare forms he has identified *Stomatopora johnstoni* and *S. incrassata*, *Tubulipora lobulata*, *Lichenopora hispida*, *Cellepora dichotoma*, *Membranipora aurita*, and a peculiar variety of *Cellaria fistulosa*.

Towards evening three very successful hauls of the dredge were made, which covered practically all the ground in a line from the southern end of the "Calf" to the northern side of Port Erin Bay, just under Bradda Head. Amongst the material obtained in these hauls the following species were noticed: *Asterias glacialis*, *Solaster endeca*, *Stichaster roseus*, *Porania pulvillus*, *Luidia fragilissima*, *Antedon rosaceus*, *Ebalia* sp., *Xantho* sp., *Pleurobranchus membranaceus*, *Ascidia venosa*, *Ascidia plebeia*, *Corella parallelogramma*, *Polycarpa* sp., *Leptoclinum* sp., and other Compound Ascidians.

In Port Erin Bay after dark the electric light was again used successfully in the bottom and surface tow-nets.

On the third day an early start was again made, with the object of leaving time to run down into the deep water lying to the south of the Isle of Man. Unfortunately, however, a thick fog was encountered, which hampered our movements during the morning and changed all the plans for the day. After passing the "Chicken" Rock, the *Hyæna* steamed slowly for Liverpool, and reached the Mersey about 1 a.m. on Tuesday. A few hauls of the trawl and dredge were taken on the way home, with no great results, and the tow-nets, both bottom and surface, were worked whenever practicable.

The important feature of this cruise, however, was the use which was made of the electric light for collecting after dark. On the first night, in Ramsey Bay, after the shore party had left and the ship was anchored for the night, an electric light of 1000 candle-power was hoisted a few feet above deck, and this allowed work to be carried on almost as comfortably as during the day. Captain Young, of the Liverpool Salvage Association, who was in command of the *Hyæna*, then kindly arranged for me a 60 candle power Edison-Swan submarine incandescent lamp in the mouth of a tow-net. This illuminated net was carefully let down to a depth of 3 fathoms, and allowed to remain there for half an hour. At the same time, another tow-net without any light was let down to the same depth over the opposite side of the ship. When the nets were being hauled in, as the one with the electric light approached the surface numerous small animals (Crustacea probably) were noticed accompanying it, and darting about in the bright light. This tow net, when emptied into a glass jar of sea-water, was found to contain an abundant gathering, consisting mainly of Crustaceans; while the net in the dark on the other side of the ship had practically nothing.

The two nets were then put out again. The one had the electric light in its former position, but this time it was let down to the bottom at a depth of 6 fathoms; while the other net was placed in the dark at the ship's stern, and also reached the bottom. The tow-nets remained stationary, but were kept distended by the tide. The outline of the illuminated net could be made out indistinctly at a depth of 6 fathoms. After being out for three-quarters of an hour, both nets were hauled in, with the same result as before. The illuminated net contained abundance of Crustacea (chiefly Amphipoda, Schizopoda, and Cumacea), while the dark net again contained practically nothing. These two experiments showed pretty conclusively the effect of the brilliant light in attracting the free-swimming animals, the difference between the contents of the two nets being on both occasions most marked. Consequently, on the second night, in Port Erin Bay, *both* nets were illuminated, and while the one was let down close to the bottom, at a depth of 5 fathoms, the other was kept at the surface of the sea on the opposite side of the ship. This experiment was tried three times, with the same result each time: both the nets were found to contain abundance of animals, but the bottom and surface gatherings differed greatly in appearance and in constitution. The net from the bottom contained mainly large Amphipoda, and some Cumacea, while the gathering from the surface was characterized by the abundance of Copepoda. As Mr. A. O. Walker, who is reporting upon our higher Crustacea, pointed out to me, the Amphipods from the deep net appeared to be chiefly red-eyed species, such as *Ampelisca lævigata* and *Bathyporeia pilosa*. If this, on a detailed examination of the material, turns out to be the case, it may indicate an interesting relation between the colour of the eyes and sensitiveness to the electric light.

Mr. Thompson has already identified the following species of Copepoda from the illuminated surface net: *Calanus finmarchicus*, *Pseudocalanus elongatus*, *Dias longiremis*, *Idya furcata*, *Centropages hamatus*, *Anomalocera patersonii*, *Isias clavipes*, *Oithona spinifrons*, *Harpacticus chelifer*, and *Harpacticus fulvus*. The specimens of the last two species are remarkable for their unusually large size and their abundance.

The various groups of animals collected will as usual be worked up in detail by specialists, and the results will appear in future L.M.B.C. Reports; but the application of the electric light to marine biology, as a bait or attraction in the tow-net worked after dark, seems of sufficient importance to warrant the publication of this preliminary account of the results of the *Hyæna* cruise of Whitsuntide 1888. The obvious extension of this illumination method to deep-water tow-netting and trawling during the day-time I hope, thanks to the kindness of the Salvage Association, to be able to experiment upon in a future expedition.

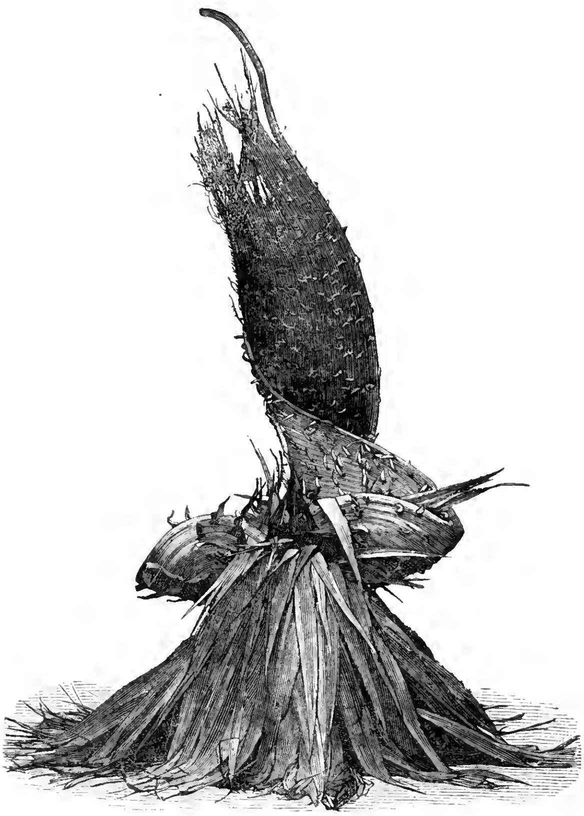
W. A. HERDMAN.

A REMARKABLE CASE OF FASCIATION IN FOURCROYA CUBENIS, *HAW*

THERE was lately exhibited in this city a plant of *Fourcroya cubensis*, Haw., in which the well-known, tree-like inflorescence had been deformed into what I believe to be the largest fasciation on record. The plant came from Carapa, a small village distant about 4 miles towards the west from Caracas. Its aspect is given in the accompanying figure, engraved after a photograph.

The stem of the plant, covered by the leaves, is about 1 metre in height. From between the upper leaves there branch out two flattened and curiously twisted bodies. The one to the left was soon checked in its growth, so that it forms but little more than a semicircle; whilst the other, after having described a curve somewhat like a very large capital S, rises to a height of about 4 metres from the soil. Both together have in the front view the appearance of a small boat with hoisted sail filled by the wind. The under and lower parts of this deformed flower-stem are covered by numerous bracts, and measure 80 centimetres in their greatest breadth. Towards the top it divides into shred-like branches bearing flower-buds; those of the latter I examined being in every respect of normal structure.

There can be little doubt that, in this case, the malformation is due to some injury done to the young flower-stem, when it was scarcely 1 foot high, vestiges being still visible that it was bent towards the right and kept in this forced position by some of the leaves. The upward growth being thus checked, numerous adventitious buds made their appearance on the injured organ, coalesced from the very outset, and formed by their subsequent growth the fasciated stem, the twisting resulting from the unequal rate of development of its component parts (Masters, "Veget. Teratology," 18).



Fasciation is likely to be not at all uncommon in *Fourcroya* and other allied plants, though I know of but three cases in the former, and never heard of any in *Agave*. In 1854 a very curious case of this kind was for several months the cause of considerable excitement among the good people of Caracas; it is described in the newspapers of the time as having been likewise twisted in the shape of a gigantic S. Another instance came under my notice in 1876, and was described in the *Journal of Botany* of that year, p. 180.

Caracas, April 19. A. ERNST.

NOTES.

THE following were elected Foreign Members of the Royal Society, on Thursday, May 31: Prof. Edmond Becquerel, of Paris, distinguished for his researches on the effects of light on bodies, especially with reference to phosphorescence; Prof. Hermann Kopp, of Heidelberg, for his researches on atomic volumes and boiling-points; Prof. Eduard F. W. Pflüger, of Bonn, for his researches in physiology, especially in relation to irritability of nerves, respiration, and animal heat; and Prof. Julius Sachs, of Würzburg, for his researches in botany, especially vegetable physiology.

THE Board of Visitors made their annual inspection of the Royal Observatory at Greenwich on Saturday last.

THE Vienna Correspondent of the *Times* announces that, in pursuance of a resolution passed at a recent meeting, the Vienna geologists will invite the International Geologists' Congress, which will assemble in London in September, to hold its next meeting in Vienna.

AT a recent meeting of the Victoria Royal Society, the President (Prof. Kerrot) announced that the first meeting of the Australian Association for the Advancement of Science would be held at Sydney, beginning September 4, the second at Melbourne, the third at Adelaide. The proposal that Victoria should join in the movement was favourably received, but at that meeting no action was taken in the matter.

IT will be seen from our list of the additions to the Zoological Society's Gardens during the past week that a living specimen of Pallas's sand grouse (*Syrrhaptes paradoxus*), the new visitor from Central Asia, has been presented by Mr. H. Hewart Crane, of Berwick-on-Tweed. It was captured at that place on May 25.

THE Tartar sand grouse seems to have appeared in Denmark and Scandinavia before making its appearance here. In the Island of Bornholm, in the Baltic, large flocks, numbering many hundreds, were seen early in May, some being shot, others captured alive. A few days later, birds were seen in various parts of Denmark and Sweden. In Norway a flock of birds was seen at Lister, on the extreme west coast, on May 12, and two were shot, a male and female. Their crops were full of tiny black seeds unknown to that country, whilst the eggs in the hen were far developed. During the immigration in 1863 these birds were seen as far north as Nordfjord. In that year, too, many nested on the west coast of Jutland, where the soil is sandy, but they were all gathered by the fishermen.

PROF. A. GRAHAM BELL, who is now on his way to England, will shortly appear before the Royal Commission engaged in making inquiry as to the best methods of caring for and educating deaf-mutes. In announcing this fact, *Science* reminds its readers that several years ago Prof. Bell presented a paper, at a meeting of the National Academy of Sciences, on the formation, through the intermarriage of deaf-mutes, of a deaf variety of the human race, and gave some important statistics to show that a much larger percentage of the children of deaf parents are deaf than of those whose parents possess the sense of hearing. This paper attracted wide attention, and gave rise to very interesting discussions both in America and elsewhere. The Royal Commission has requested Prof. Bell to lay before it the results of his subsequent investigations and studies upon this branch of the subject, and he has devoted much time to the preparation of facts and figures in regard to it. He will also give the Commission the result of his studies of other divisions of the subject.

ACCORDING to *Allen's Indian Mail*, Mr. Barrington Browne, the geologist sent by the Secretary of State to examine the Burma Ruby Mines, has left Simla for England. He has, it is understood, handed in to the Government of India his report on the mineral wealth of Upper Burma.

THE hydrographic survey of Canadian waters, which has already taken about five years, is now nearly half done. Commander Boulton is hard at work in Georgian Bay, one of the most dangerous of inland waters in Canada, and it is said that the survey will be extended to Lake Superior.

FROM September 15 to October 25 there will be in Vienna an International Exhibition of Amateurs' Photographs and Photographic Apparatus. The Exhibition is being organized by the Vienna Club of Amateur Photographers, and will be held in honour of what is called "the Jubilee" of the Emperor Francis Joseph. It will include every branch of art and manufacture connected with photography. The Club's Daguerre Medal and certificates of honourable mention will be awarded to the best exhibit or exhibits in each class of photography, photographic apparatus, lenses, &c., provided the jury deem any exhibit or exhibits of sufficient merit. From the decision of the jury there will be no appeal. The Club, as far as its funds permit, will purchase the most interesting exhibits. Amateurs have not to pay hire for the space allotted to them. On application they can obtain the use of frames free of charge. A catalogue will be published, possibly with illustrations of the most interesting objects. According to the statutes of the I. and R. Austrian Museum for Arts and Manufactures, admission will be free five days a week.

THE current number of the *Board of Trade Journal* contains an abstract of the third volume of the Reports of the Royal Commission appointed by the King of the Belgians in April 1886 to inquire into the condition of labour in Belgium. The volume contains the propositions of the various sections of the Commission with respect to the different questions relating to the condition of the working classes, and also the final conclusions of the whole Commission. The third section of the Commission dealt with technical education, and the conclusions adopted by the whole Commission are as follow :—(1) They recommend that in the technical schools practical lectures be given on the application of art and science to industry. (2) Manual dexterity should be cultivated in the elementary schools. At the industrial schools the theoretical application of science to industry should be taught. (3) The Government should limit its action to providing grants for these schools, and fixing the position each school is to occupy in a proper gradation of educational institutions. (4) The local bodies should introduce manual exercises into the primary schools, and found more technical schools and schools of design and modelling. (5) The aid of the Government and the communes should be given conditionally on a minimum age being fixed for apprentices, and on a test examination at entrance being made necessary. (6) The Government should aid in increasing the facilities by which workmen would get technical instruction in subjects suited to their occupation.

M. COUMBARY, Director of the Imperial Meteorological Observatory at Constantinople, has published a pamphlet upon the climatology of that place, deduced from twenty years' observations (1868–87). Hitherto, what has been known about its climate is mostly owing to observations and summaries contained in the periodicals of the French Meteorological Society, commencing with the year 1847, and to the telegraphic reports in the French *Bulletin International*. M. Coumbary issued a monthly Bulletin in 1869, containing observations made at several places in the Ottoman Empire, but this was discontinued in 1874. The present discussion shows that the mean temperature is 57°·7. The absolute maximum was 99°·1 in August 1880, and the minimum 17°·2 in January 1869, giving a range of 82°. The French observations show greater extremes, but this is probably owing to imperfect protection from radiation in earlier years. The greatest daily ranges were 37°·8 in December, and 36° in March ; in other months the range has not exceeded 27°. The extremes are of course modified by the influence of the Black Sea ; it is not unusual for the thermometer at Odessa, for instance, to indicate 24° or so below the temperature at Constantinople. The mean annual rainfall is 28 inches, and the days of rain average 84. Snow falls on 14 days, on an average. About three years ago the Sultan showed his interest in the subject by the establishment of a second observatory in his palace at Yildiz. Both institutions are furnished with the best instruments.

WE have received the twelfth Annual Report on the Meteorology of India, containing the observations taken in 1886. It deals with nearly the same area as last year, and is published in the form previously adopted. For fullness and thoroughness in the discussion of results, it remains unexcelled, and it includes, as before, monthly charts showing very clearly the mean pressure and temperature, and the resultant winds over the vast region embraced in the Report. Among the more important additions are an observatory at Mandalay, where the transitions of the seasons are said to be sudden, and earthquakes not infrequent, and a station on the Great Coco Island, in the Bay of Bengal, an island which is said to be destitute of drinking-water. The results show that in every month of the year 1886 the mean "equilibrium" temperature of insolation throughout India was below the average of the last ten or eleven years by amounts varying from 0°·8 to 1°·8. The annual variations for the past seven years show a fairly well-marked periodicity, and suggest a slight variation in the sun's radiating power. The rainfall is represented by 500 stations (14 more than in the previous Report), and was characterized by several striking features. On the mean of the whole area there was an excess of 2·77 inches as compared with the averages for previous years.

THREE important new chlorine compounds of titanium have been obtained by Drs. Koenig and von der Pfordten, of Munich. They may be considered as chlorine derivatives of titanic acid, $Ti(OH)_4$, and form the only complete series of such compounds with which we are as yet acquainted in the whole range of inorganic chemistry. They are formed by the replacement of the hydroxyl groups by chlorine, and have therefore the following constitutions: $TiCl(OH)_3$, $TiCl_2(OH)_2$, and $TiCl_3OH$. The well-known tetrachloride of titanium, $TiCl_4$, thus completes the series, and in reality formed the starting-point from which the three intermediate compounds were successively prepared. Trichloride of titanic acid, $TiCl_3OH$, was obtained by the careful addition of concentrated hydrochloric acid to the tetrachloride in such proportion that the amount of water present in the strong acid was that required by the following equation: $TiCl_4 + H_2O = TiCl_3OH + HCl$. The reaction is very violent, and a solid mass of the trichloride was almost instantly formed and considerably distended by the escaping hydrochloric acid gas. The substance was at once transferred to the vacuum of an air-pump, and after a few days was found to be entirely freed from last traces of the gas. The solid trichloride thus formed is extremely deliquescent, and readily dissolves with considerable hissing in water and alcohol, the aqueous solution being remarkably stable. The dichloride, $TiCl_2(OH)_2$, was prepared by addition of a slight excess of strong hydrochloric acid to the tetrachloride, and also by placing the latter compound in a small quantity of ice-cold water. In the latter case, the drops of $TiCl_4$ are at first decomposed with loud hissing, which, as the drops continue to fall, gradually diminishes until a point is reached when a drop floats on the surface and remains unattacked. This last drop is then removed, and the clear solution evaporated *in vacuo*, when the dichloride is left as a compact deliquescent solid. The monochloride, $TiCl(OH)_3$, is the product of the action of moist air upon the tri- and di-chlorides, hydrochloric acid gas being at the same time evolved, in accordance with the following equations :

$$TiCl_3OH + 2H_2O = TiCl(OH)_3 + 2HCl,$$
$$TiCl_2(OH)_2 + H_2O = TiCl(OH)_3 + HCl.$$

The monochloride thus formed remains stable in air ; on evaporation over oil of vitriol it is obtained as a white solid, crystallizing apparently in the hexagonal system, and very difficultly soluble in water. In conclusion, the Munich chemists show very conclusively that these new substances are true compounds and no mere mixtures ; and, it may be added, the analyses, which must of necessity have been extremely difficult, are quite satisfactory.

THE British Consul at Mogador, in Morocco, in his last report notes, in connection with the fisheries of the year, a curious phenomenon. A fish locally called the "tasargelt" (*Temnodon saltator*) has appeared in vast shoals, having left the waters unvisited, save a few stray specimens, since 1859. It weighs from six to eight pounds, and has flesh of rich flavour, of which the natives never seem to tire. It first appeared in large numbers early in September, and from that time till December the fishermen were busily occupied taking them. The mode of capture is rather primitive. A piece of white rag or a strip of the skin of the tasargelt itself is fastened to a large and often barbless hook, which in turn is tied by strong brass wire to the end of a short bamboo rod. When the bait is drawn rapidly through the water, the fish rises quickly to it. The tasargelt was accompanied by shoals of the "azlimzah" or "maigre," a fish which frequently weighs as much as sixty or seventy pounds. The presence of these voracious fish ruined the ordinary hook-and-line industry. Though shoals of bonito appeared, only one small specimen was taken, for they refused to take any bait. The sardine fishery was also a failure.

THE British Consul at Varna, in the course of his Report on the trade of his district for the past year, refers to the vineyards, and says that, though the Phylloxera has not made its appearance in these regions, there is a kind of insect pest which he believes to be peculiar to the Varna vineyards. Its ravages have been confined to certain areas, and the vine it attacks is disabled only for the year of the attack, and only to the extent of the particular shoots which it may lop off. The local name of the insect is *Kara terzi*, or "the black tailor," an appellation which is supposed to indicate its appearance and habits. In the absence of local entomologists, Mr. Brophy describes this new pest as an adipose black beetle, somewhat resembling the ordinary dung-beetle, measuring, when adult, about three-fourths of an inch in body-length, and furnished with a short pair of shears; with these, in the mornings of April and May, it cuts through and off the young vine-shoots, which it leaves on the ground until they are parched by the sun, when it drags them into the recesses of its deep and tunnelled hole, generally situated at the foot of the plant attacked. The vineyards chiefly affected are situated on ground near the sea-shore, whence the insect makes its way inland; "and as the *Kara terzi* does not appear to have obtruded itself upon the notice of the vine-growers by its obnoxious habits until comparatively recently, it may perhaps be fair to suppose that the temptation of green and succulent vine-shoots may, in the course of generations, have perverted the present race into abandoning the more innocent diet which satisfied their ancestors, and which, when the vine-shoots have passed the tender stage, has still to suffice those of the present day." Mr. Brophy says that if the circumstances of insect-life here related prove in any way new or interesting, it would not be difficult to procure, in summer, specimens of this beetle for inspection by qualified entomologists.

AT two successive meetings of the Oriental Society of Pekin, Prof. Russell, of the Tung-Wen-Kwan, or Foreign Language College, read two papers on subjects connected with Chinese astronomy. In the first he described the instruments in the Pekin Observatory, which were constructed by the order of the great Emperor Kanghi about 1670. In the course of the discussion which followed, it was stated that this prince was very fond of mathematics and astronomy, and that the present Emperor was credited with similar inclinations. Kanghi was sixteen when he ordered the instruments to be constructed. The clepsydra used in the Observatory, it was stated, consisted of five cisterns, and was used for observing the time of eclipses, being put in order for this purpose three days before each eclipse. One of the instruments is usually said to be of European design and to have been presented by Louis XIV. The inscription or emblem on it has been carefully removed, and its place supplied by a piece of bronze matching the metal of the instrument. In some Chinese books it is said that this instrument was manfactured by a foreign priest. Verbiest, a Jesuit of the time of Kanghi, pointed out a mistake in the Chinese calendar; the matter was referred by the Emperor to the Board of Astronomy, and Verbiest's accuracy was acknowledged. From that time a Jesuit missionary occupied the post of Vice-President of the Board down to 1828.

THE second paper, also by Prof. Russell, was on early Chinese eclipse calculations, and entailed vast labour in re-calculating. It appears from the investigations of the learned Professor that the earliest calculations of a solar eclipse and also of a lunar eclipse which have been preserved were made by the Chinese. The discussion turned largely on the historical value of the Chinese classics with regard to these astronomical observations, and the attention with which the Chinese from the earliest times have studied astronomy. Passages found in one or other of the few works which survived the destruction of the books before the Christian era bear witness to the devotion with which the stars were studied in China at that remote epoch. The full text of these two interesting papers will be awaited with interest.

AT a recent meeting of the Scientific Society of Upsala, Dr. C. Aurivillius read a paper on the skeleton of the so-called Swedenborg whale (*Eubalena svedenborgii*, Lillj.), discovered last November in the province of Halland, in a layer of marl 50 feet above the sea. Remains of this species of whale have only been found once before, viz. early last century, when some parts of one were discovered in the province of Western Gothland, 330 feet above the sea, and 70 miles inland. It was at first believed that they were the bones of some giant, but it is said that Swedenborg discovered their true nature. The skeleton has been presented to the Upsala Museum.

IN the Proceedings of the Moscow Archæological Society, there is a most interesting communication by M. Anutchin, on the use of sledges, boats, and horses, or saddles, at the burials of various races. He shows that until the seventeenth century the Slavonians used sledges even in summer for the transport of the corpse to the grave. The Samoyedes and Ostyaks, and many Russian peasants of Northern Russia, still follow this custom. The boat was used by the Normans, the Old Germans, and generally by races inhabiting the shores of lakes. Many tribes of North America used to bury their dead together with a horse, or transported the dead to the grave on a horse. It is remarkable that the same custom is found among the Lithuanians, who, even in the sixteenth century, put their dead on a saddle. The sledge, the boat, and the horse, or saddle, were obviously intended to aid the dead in passing into another world, and in visiting kinsfolk there.

AN ancient canoe has been found in the Tunhövd Fjord, in Valders, in South Central Norway. It has been hollowed out by means of red-hot stones, and is $4\frac{1}{2}$ metres long and 80 centimetres broad. It is in fair condition. The find is of interest, as no other primitive vessel of the kind has been found inland in Norway. The boat will be sent to the Museum at Christiania.

Science says that a citizen of the United States, who has long resided abroad, proposes to give to the Smithsonian Institution a large collection of armour from the Middle Ages—some of it connected with most famous historical names—including horse-armour, helmets, swords, and all the paraphernalia of ancient warfare. These objects, numbering about five thousand, have been brought together at great expense, and the collection is one of the most valuable of the kind in the world. The condition of the presentation is that the Smithsonian Institution shall furnish a fire-proof building for the collection.

At the last meeting of the Ceylon Branch of the Royal Asiatic Society, a lengthy paper was read by Mr. P. Ramanathan, the leading Tamil of Colombo, on the ethnology of the Moors of Ceylon. These Moors, or Moormen, are usually classified in the island as a race by themselves, apart from the Tamils, Singhalese, and other races inhabiting it, but Mr. Ramanathan came to the conclusion that the history, social customs, physical features, and language of the Moors, class them as Tamils who were converted to Mohammedanism in India before their migration to Ceylon. He does not think there is any difference between the two classes of "Ceylon Moors" and "Coast Moors" in race or in the history of their conversion, the difference drawn by the members of these classes between themselves being due to a break in the course of immigration from India caused by the persecution of Mohammedans by the Dutch when the latter had possession of Ceylon. He pointed out that it was impossible that the very large number of Moors now existing in India and Ceylon could be, as is popularly supposed, descendants of the small bands of Arab and Moorish merchants and refugees who visited India in early times. He thought that only about 5 per cent. of the existing Moors could owe their origin to these immigrants. The paper, which was a very long and exhaustive one, evidently could not be fully appreciated by those who merely heard it read; but in the subsequent discussion most of the speakers appeared to think that Mr. Ramanathan's conclusion was not satisfactorily established. It was argued that in several directions—especially in regard to the shapes of the skulls—the facts were insufficient, and that at best Mr. Ramanathan's evidence for his thesis was only secondary. The value of the paper as a starting-point for further investigation was generally acknowledged.

The *Comptes rendus* of the French Academy of Sciences for May 14, publishes some interesting remarks on the vital statistics of Germany, by M. Ch. Grad, author of a work on the power and resources of the German people. The population of the empire increased from 40,816,000 in 1870 to 46,855,000 in 1885; that is, an increase of over 6,000,000 in fifteen years, or at the rate of 1 per cent. per annum. Compared with this the increase in France has been extremely slow, less than 5,000,000 for the period of fifty years between 1831 and 1881 (32,560,000 and 37,321,000 respectively), or at the rate of only 0·3 per cent. per annum, with a constant tendency to diminish. During the last fifteen years the excess of births over deaths has been seven times greater in Germany than in France. The contrast becomes greater when it is added that, while few Frenchmen emigrate, as many as 4,000,000 Germans have removed to the United States since 1820. In 1880, the population of the empire included 2,860,000 of Polish speech, 300,000 of French, 150,000 of Danish, 150,000 of Lettish, 137,000 of Wendish, and 34,000 of Checkish or Bohemian. But on the other hand there are at present in Europe over 60,000,000 of Germanic speech, if the 8,000,000 Dutch and Flemish speaking inhabitants of the Low Countries be included. Altogether, the Teutonic nationality has doubled in Europe since 1840. But the increase has been almost entirely in the urban population, which advanced from 14,790,000 in 1871 to 18,720,000 in 1880, while that of the rural districts remained almost stationary (26,219,000 and 26,513,000 respectively). For the whole empire the density of the population is about 86 per square kilometre as compared with 72 in France.

Some figures with reference to alcoholism and criminality were recently communicated to the French Academy of Medicine by M. Marambat. They referred to an examination of 3000 condemned persons; and it appears that 79 per cent. of the vagabonds and mendicants were drunkards, 50 to 57 per cent. of assassins and incendiaries, 53 per cent. of persons convicted of outrages on morals, 71 per cent. of thieves, sharpers, &c. In acts of violence against the person, 88 per cent. were found to be drunkards; against property, 77 per cent. Among youths under twenty, drunkards were nearly as numerous as among adults, the difference being only 10 per cent. Of these youths, 64 per cent. were addicted to drinking. An examination of the departments showed the largest number of drunkards from the regions where spirits are most largely consumed.

A fifth edition of the late Prof. Balfour Stewart's "Elementary Treatise on Heat" (Clarendon Press) has just been issued. Prof. Tait undertook to read the proofs, but found that there was little for him to do. "Prof. Balfour Stewart had himself," he says, "given *imprimatur* to all but the last six sheets; and for these I was furnished with 'copy' (excepting four pages) fully revised and initialed by him. The book is published, therefore, precisely in the form in which its author intended it to appear."

The February and May numbers of the Journal of the Anthropological Institute are of more than usual interest. Among the contents are the following papers: on an ancient British settlement excavated near Rushmore, Salisbury, by General Pitt-Rivers; on the stature of the older races of England, as estimated from the long bones, by Dr. John Beddoe; the Lower Congo, a sociological study, by Mr. R. C. Phillips; the origin and primitive seat of the Aryans, by Canon Isaac Taylor; the Maori and the Moa, by Mr. E. Tregear; on the shell money of New Britain, by the Rev. Benjamin Danks; on tattooing, by Miss A. W. Buckland; on the evolution of a characteristic pattern on the shafts of arrows from the Solomon Islands, by Mr. Henry Balfour; on the occurrence of stone mortars in the ancient (Pliocene?) river-gravels of Butte County, California, by Mr. Sydney B. J. Skertchly; and the address delivered by Mr. F. Galton, as President, at the anniversary meeting of the Institute.

Messrs. John Wiley and Sons, the American publishers, have in preparation a translation of Rosenbusch's "Microscopical Physiography of Minerals and Rocks," by Joseph P. Iddings, of the United States Geological Survey.

Last week we referred to the edition of Barlow's Tables of Reciprocals issued by Taylor and Walton in 1840. The work has also been issued by E. and F. N. Spon. With reference to our note on this subject, Mr. V. B. Sprague and Mr. George King call attention to the "Table of the Reciprocals of Numbers from 1 to 100,000, with their differences, by which the reciprocals of numbers may be obtained up to 10,000,000, by Lieut.-Colonel W. H. Oakes, A.I.A. London: Charles and Edwin Layton, 150 Fleet Street, 1865." This table gives to seven significant figures the reciprocals of all numbers from 10,000 up to 99,999; and by means of the proportional parts the reciprocals of all numbers up to 10,000,000 may be obtained. Mr. Sprague points out that reciprocals can also be obtained with great facility by the use of Thomas's arithmometer; and this, he thinks, is the most convenient method when the number contains eight digits, and it is desired that the reciprocal should contain the same, or a larger number, of significant figures.

A Russian translation of Prof. Everett's "Units and Physical Constants" has just been published at St. Petersburg. This is the fifth language into which the work has been translated, the other four being Dutch, French, Polish, and German. The German edition was long delayed by the compiling of additional experimental data, and only made its appearance a month ago.

The New York State Museum of Natural History has issued a useful Bulletin (No. 3) on "Building-Stone in the State of New York." The author is Mr. John C. Smock.

THE additions to the Zoological Society's Gardens during the past week include a Pudu Deer (*Pudu humilis* ♀) from Chili, presented by Mr. G. E. Pugh Cook; two —— Squirrels (*Sciurus* ——) from Demerara, presented by Mr. R. Forrester Daly; a Blue and Yellow Macaw (*Ara ararauna*) from South America, presented by Mrs. Alfred Palmer; a Pallas's Sand Grouse (*Syrrhaptes paradoxus*) from Berwick-on-Tweed, presented by Mr. H. Hewart Crane; two Australian Waxbills (*Estrelda temporalis*); seven Spotted-sided Finches (*Amadina lathami*) from Australia, presented by Mr. David S. Hodge; a Nose-crested Iguana (*Iguana rhinolopha*) from St. Lucia, West Indies, presented by Dr. T. Dennehy; a Tent Tortoise (*Testudo tentoria*), a Fisk's Tortoise (*Testudo fiski*) from Cradock, Cape Colony, a Dwarf Chameleon (*Chamæleon pumilus*), a Purplish Gecko (*Phyllodactylus porphyreus*), a Hoary Snake (*Coronella cana*), three Narrow-headed Toads (*Bufo angusticeps*), five Gray's Frogs (*Rana grayi*) from South Africa, presented by the Rev. G. H. R. Fisk; two Tigers (*Felis tigris*) from India, two Puff Adders (*Vipera arietans*) from South Africa, deposited; a Long-billed Butcher Crow (*Barita destructor*) from New Holland, received in exchange; two North African Jackals (*Canis anthus*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *JUNE* 10–16.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 10

Sun rises, 3h. 46m.; souths, 11h. 59m. 15·5s.; sets, 20h. 13m.: right asc. on meridian, 5h. 16·3m.; decl. 23° 4′ N. Sidereal Time at Sunset, 13h. 31m.

Moon (New on June 9, 17h.) rises, 4h. 35m.; souths, 12h. 40m.; sets, 20h. 49m.: right asc. on meridian, 5h. 57·3m.; decl. 20° 45′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. and declination on meridian. h. m.	° ′

GEOGRAPHICAL NOTES.

MAJOR HOBDAY reports of the operations in Upper Burma that during the season of 1887–88, the whole of the Yaw country has been thoroughly surveyed by surveyors attached to the various columns converging on Gangaw. On the north a connection has been made with the work executed by Colonel Woodthorpe's party last year in the Kubo Valley. A good deal of the geography of the Schwele River and the Mohlaing district has also been obtained. The extent of surveying that has been done by the surveyors who accompanied the column from Bhamo to Mogdung and thence by the Jade Mines and Endawgyi Lake to Katha, on the Irrawaddy, is not yet known, as reports have not yet been received. In the Southern Shan States a party under Lieut. Jackson, R.E., has carried on survey operations in continuation of last year's work from Fort Stedman to Pekon, in the Saga Valley, thence *viâ* Maukme, and Moné to Maing-pan and the Salween River, where the Siamese mission under Mr. Archer was met. Returning to Moné, they carried the survey through Legya and Bansan to Maing-ye. In the Northern Shan States a sub-surveyor has carried our surveys from Thibaw to Namsan, and across the Myit-nge or Namtu River to Theinni, on the Salween, and thence *viâ* Maing-yaw to Manse and Maing-ye, thus effecting a junction with Lieut. Jackson's work. Major Hobday himself has extended the triangulation from Kyan Nyat to Bhamo, of which the position is thus determined, and a basis provided for the surveys in the direction of Mogaung. It is hoped that the triangulation executed by this party will be connected during this season with that of the surveys in Lower Burma. In addition to the work done by members of this department, many reconnaissances have been executed by regimental and other military officers and the results given to Major Hobday for incorporation in his sheets.

WE are glad to notice that Signor Guido Cora's *Cosmos* now appears more regularly and frequently than formerly. The last number contains a detailed account of recent Danish expeditions in Greenland.

THE whole of the new number of the *Deutsche Geographische Blätter* is occupied with the narrative of J. G. Kohl's American studies, the results of journeys made thirty years ago in North America.

THE principal paper in the new part of the *Zeitschrift* of the Berlin Geographical Society is an elaborate examination of Sir John Mandeville's writings by Dr. A. Bovenschen, in which the author comes to conclusions decidedly unfavourable to Sir John's trustworthiness. Dr. G. Hellmann contributes an important paper on the rainfall of the Iberian peninsula. In the *Verhandlungen* of the same Society we find papers on the geography and ethnography of Southern Mesopotamia, by Dr. B. Moritz, and on the Isthmus of Corinth, by Dr. A. Philippson.

IT may be useful to state that in No. 1 of the third series of the *Bulletin* of the Egyptian Geographical Society is a connected account in French, by Dr. O. Lenz, of his last journey across Africa.

THE June number of the Journal of the Royal Geographical Society contains the first part of Mr. D. W. Freshfield's paper on the Caucasus; it deals with Suanetia, and is illustrated with maps and diagrams. The same number contains Mr. Woodford's paper on his explorations in the Solomon Islands.

TWO Swedish colonists, MM. Valdau and Knutson, have recently done some interesting geographical work in the Cameroons territory. M. Valdau has explored the northern slopes of the range, which are very thickly peopled by the Bomboko tribe. The main chain of the mountains does not extend as far as 4° 30′ N. lat., as the highest point attained by the traveller, about 4° 28′ N. lat., only measured 2850 feet. M. Knutson has explored the River Memeh, which, he ascertained, empties itself into the sea a little to the south of Rumbi. The river is navigable for thirty miles, to the Düben falls, which are 100 feet in height.

BIOLOGICAL NOTES.

FOSSIL FISH REMAINS FROM NEW ZEALAND.—Mr. Davis has recently described a number of fish remains from the Tertiary and Cretaceo-Tertiary formations of New Zealand. The memoir forms a part of the Transactions of the Royal Dublin Society, and is illustrated by seven well-executed plates of the fossils. Some short time ago Mr. Davis received the remains of some fossil Tertiary Elasmobranchs from Prof. F. W. Hutton, from New Zealand, which formed the subject of a short communication to the Geological Society of London; but a much larger collection having been in the meanwhile received, permission was granted for the withdrawal of the paper, and now, based on several additional collections, we have the present memoir, which for the first time does justice to these interesting fossil forms by full descriptions and excellent figures. The memoir opens with an account of the Tertiary formations of New Zealand, based on the results attained by the Geological Survey under Sir James Hector, while notice is taken also of the views of Prof. Hutton and Sir J. von Haast. In addition to the remains of fish, some Saurian teeth, as well as those of a Squalodon, have been found. Of the thirty-five species of fish described, no less than twenty-eight appear as new species; of these thirty-five, twenty-eight are Sharks, four are Rays, two belong to the Chimerids, and one to the Teleostei. A new species of toothed Whale, *Squalodon serratus*, is also described.—(Transactions of the Royal Dublin Society, vol. iv. (ser. 2), part i. pp. 1–50, plates i.–vii.)

MAMMALS OF LIBERIA.—Dr. F. A. Jentink continues his account of the recent zoological researches in Liberia, which have been carried on for the last seven or eight years by J. Büttikofer, C. F. Sala, and F. X. Stampfli. The amount of information collected by the first-named investigator is very great, and merits the high praise bestowed upon it by the Director of the Leyden Museum. Of the ninety species of Mammals sent home, thirteen belong to the Monkeys, eleven to the Carnivores, thirty-three to the Ruminants, five to the Pachyderms, twenty-five to the Rodents, one Sireniad, four Insectivores, seventeen to the Bats, and three to the Edentates. Among the more interesting species mentioned are the following: *Cercopithecus stampflii*, n. sp., from Pessy Country; *Terpone longiceps*, Gray; *Cephalophus doria*, Ogilby, and *Euryceros euryceros*, Ogilby; *Graphiurus nagtglasii*, n. sp.; *Claviglis crassicaudatus*, n. g. et n. sp.; *Crocidura buttikoferi*, n. sp., and *C. stampflii*, n. sp.; *Pachyura megalura*, n. sp.; *Epomophorus veldkampii*, n. sp.; and *Vesperugo stampflii*, n. sp. This number also contains notes of 151 species of Birds, collected by J. Büttikofer and F. X. Stampfli, during their last sojourn in Liberia. The last-named is still collecting on the Farmington River, a large confluent of the Junk.—("Notes from the Leyden Museum," vol. x. Nos. 1 and 2, January and April, 1888.)

ON NEW ENGLAND MEDUSÆ.—In a list of certain Medusæ, found by Mr. J. Walter Fewkes, off the coast of Maine and from Grand Manan, he redescribes and figures the interesting and beautiful *Nanomia cara*, A. Ag. This Physophore, described some twenty-five years ago, though repeatedly referred to in text-books and general works on zoology, seems to have since escaped attention, but many specimens were found at Grand Manan. It will be remembered that the form thought to be adult by A. Agassiz, is not above six inches in length, but Mr. Fewkes captured specimens measuring, when extended, over four feet in length, and three feet when retracted; while many hundreds were seen of the size of the specimen he figures, which is about sixteen inches long. When floating in the water they were easily distinguished from the southern Physophore, *Agalma elegans*; the nectocalyces are biserial, the specimen figured has thirteen pairs of well-developed bells, and many of the adults had fifteen pairs. Among the most interesting and it would seem exceptional structures in this form are the organs referred to by A. Agassiz as the "third kind of polyps," now called "hydrocysts" or "tasters"; these hang from the polyp stem midway between the polypites, a single adult and many half-developed tasters occurring between each pair of polypites. They are small, slender, flask-shaped bodies, the distal end is closed, and near the basal attachment there is a prominent red body of spherical shape, known as the "oil globule"; each taster has also a single long tentacle. Contrary to what A. Agassiz thought, the adult Nanomia has male and female bells on one and the same colony; each female bell carries a single ovum, which, when they escaped, could be easily seen by the unassisted vision. *Hydrichthys mirus*[1] is also described and figured as a new genus and species belonging to the Hydroida; it was found attached to the side of a small fish (*Seriola zonata*, Cuv.) which had been taken in the dip-net at a time when the sea was quiet. The patch had at first all the appearance of a Fungoid growth. The fish and Hydroid parasite were kept alive for some time in an aquarium, and from the latter many thousands of Medusæ were raised. The Hydroid colony formed a cluster of reddish and orange-coloured bodies; the basal attachment is a flat thin plate with ramifying tubes; upon it are separate clusters of gonosomes and (?) hydranths. Each gonosome is botryoidal; the free extremity of the gonosome is without tentacles, its rim is entire, and it is destitute of Medusa buds. It seems possible that no food is taken in by the gonosomes, but that the whole structure is dependent upon the tubes of the basal plate for its nutrition. The filiform structures (hydranths ?) are elongated flask-shaped bodies of about uniform size, with terminal openings. The Medusa is closely related to Sarsia, and so far shows the new Hydroid to be allied to the Tubularians, but there are not wanting certain features which hint at a kindred to the Siphonophores. The rare and interesting *Callinema ornata*, Verrill, is redescribed, and for the first time figured. With a remark of the author, "that histological researches lose some of their value if not preceded by an accurate identification or specific description of the animal studied, if it be different from known species," we heartily agree.—("Studies from the Newport Marine Laboratory," Bull. Mus. Comp. Anat. Harvard College, vol. xiii. No. 7, February 1888.)

THE BILL FOR THE PROMOTION OF TECHNICAL INSTRUCTION.

THE following is the Bill for the promotion of technical instruction, introduced by the Government:—

Be it enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:

1.—(1) Any School Board in England may from time to time supply or aid the supply of such manual or technical instruction, or both, as may be required for supplementing the instruction given in any public elementary school in its district, whether under its own management or not.

(2) Manual or technical instruction shall not be supplied or aided under this section except for such scholars as—

(*a*) are recognized by the Education Department as in attendance at a public elementary school and receiving instruction in the obligatory or standard subjects prescribed by the minutes of the Education Department for the time being; and

(*b*) (in the case of technical instruction only) have obtained from the Education Department certificates of having passed the examination in reading, writing, and arithmetic, prescribed by the standard set forth in the schedule to this Act, or an examination equivalent thereto.

(3) For the purpose of supplying or aiding the supply of manual or technical instruction under this section, a School Board shall have the same powers, but subject to the same conditions, as it has for providing sufficient public school accommodation for its district, subject to this restriction that the amount of the rate to be levied in any one year for the additional purposes authorized by this section shall not exceed the sum of *one penny in the pound*.

2.—(1) If a School Board aids the supply of manual or technical instruction in any school or schools under its own management, it shall, on the request of the managers of any other public elementary school in its district fulfilling like conditions as to the supply of manual or technical instruction in conformity with the requirements of the Department of Science and Art, and on proof of sufficient demand for such instruction in that school, aid the supply of such instruction in that school in like manner as it aids such supply in the school or schools under its own management, subject to such terms as may be agreed on or determined in pursuance of this Act.

(2) If the managers of a public elementary school in the district of a School Board object to the terms on which the School Board proposes to aid the supply of technical instruction in that school, the Department of Science and Art shall, on the appli-

[1] *Vide* NATURE, vol. xxxvi. p. 604, where we believe this genus and species were first described by the author.

cation of those managers, determine whether the terms so proposed are reasonable.

3.—(1) Any local authority empowered to carry into execution the provisions of the Public Libraries Acts with respect to the establishment and maintenance of public libraries, public museums, schools for science, art galleries, and schools for art, may from time to time supply or aid the supply of technical instruction by providing or aiding in the provision of teachers, apparatus, or buildings to such extent and on such terms as the authority think expedient, and may exercise its powers under this section either with or without exercising any of its powers under the Public Libraries Acts.

(2) Provided as follows :—

(*a*) In a district for which there is a School Board, the local authority shall not out of their own funds supply or aid the supply of technical instruction suitable for scholars receiving at a public elementary school instruction in the obligatory or standard subjects prescribed by the minutes of the Education Department for the time being, except to the extent, if any, to which the authority was so supplying or aiding before the establishment of a School Board.

(*b*) In a district for which there is not a School Board, the managers of a public elementary school shall not receive aid under this section except for scholars for whom technical instruction may be supplied or aided by a School Board in a district for which there is a School Board.

(3) The amount of the rate to be levied in any one year under the Public Libraries Acts as amended by this Act for the additional purposes authorized by this section shall not exceed the sum of *one penny in the pound*, and where the powers given by the Public Libraries Acts are exercised concurrently with the powers given by this section shall not exceed *twopence in the pound.*

4.—(1) The managers of any technical school in the district of a School Board or local authority may make an arrangement with the Board or authority for transferring their school to that Board or authority, and the Board or authority may assent to any such arrangement.

(2) The provisions of section twenty-three of the Elementary Education Act, 1870, with respect to arrangements for the transfers of schools, shall apply in the case of arrangements for the transfers of schools in pursuance of this section.

5.—Every minute of the Department of Science and Art with respect to the condition on which grants may be made for technical instruction shall be laid on the table of both Houses of Parliament within three weeks after it is made, if Parliament is then sitting, and if Parliament is not then sitting, within three weeks after the then next session of Parliament, and shall not come into operation until one month after being so laid.

6.—In this Act—

The expression "technical instruction" means instruction in the principles of science and art applicable to industries and in the application of special branches of science and art to specific industries or employments. It does not include teaching the practice of any trade or industry or employment, but, subject as aforesaid, includes instruction in the branches of science and art with respect to which grants are for the time being made by the Department of Science and Art, and any other form of instruction which may for the time being be sanctioned by that Department by a minute laid before Parliament and made on the representation of a School Board or local authority that such a form of instruction is required by the circumstances of its district.

The expression "technical school" means a school or department of a school which is giving technical instruction to the satisfaction of the Department of Science and Art.

The expression "manual instruction" means instruction in the use of tools and modelling in clay, wood, or other material.

The expression "the Education Department" means the Lords of the Committee of Her Majesty's Privy Council on Education.

The expression "local authority" means the Council, Commissioners, Board, or other persons or authority carrying into execution, or empowered to carry into execution, the Public Libraries Acts.

The expression "Public Libraries Acts" means the Public Libraries (England) Acts, 1855 to 1887, and the Public Libraries (Ireland) Acts, 1855 to 1884.

7.—This Act may be cited as the Technical Instruction Act, 1888.

SCHEDULE.

STANDARD.

Reading.—To read a passage from some standard author.

Writing.—A short theme or letter on an easy subject, spelling, handwriting, and composition to be considered. An exercise in dictation may, at the discretion of the inspector, be submitted for composition.

Arithmetic.—Fractions, vulgar and decimal, simple proportion, and simple interest.

AGRICULTURAL EDUCATION IN NORTHERN ITALY AND IN PRUSSIA.

MR. COLNAGHI, Consul-General at Florence, in the course of an elaborate Report on his district, refers at some length to agricultural education in the province of Florence. He describes especially the well-known "Academia dei Georgofili," the Tuscan Society of Agriculture, the Comizi Agrari, or Agricultural Boards, the Stazioni Agrarie, and also refers to the various institutes and schools which have been established of late years in the province. The "Academia dei Georgofili" of Florence was founded in 1753, and was the first Association of the kind formed in Italy to promote the science of agriculture. On the roll of the Academy are to be found the names of the most distinguished Italian agronomists, and the long series of its Transactions contains important papers on all points of interest connected with the agriculture of Tuscany.

The Royal Tuscan Society of Horticulture, which was established in 1854, now numbers about 700 members. Much useful work has been done by this body in encouraging the improved cultivation of fruit, vegetables, flowers, and ornamental places and by the holding of annual shows in Florence.

Each district of the province has its Comizio Agrario, the objects of which are to extend agricultural skill and knowledge, or encourage improvements, and to form a centre for the diffusion of information. The Comizi offer prizes for improvements in cultivation, hold Conferences on various subjects, and publish Bulletins containing much useful information on practical subjects. These bodies are supported by members' subscriptions, and by grants from the Minister of Agriculture and from the province. Besides the annual shows held at Florence, there are regional agricultural shows (Concorsi Agrarii Regionali), instituted by the Ministry of Agriculture and the Comizi Agrari, which are held at stated periods, and in which some five or six provinces are included. These larger shows have been useful in bringing agriculturists from various parts of the country together, showing the latest improvements in machinery, and in displaying the various products of the different districts.

At the "Stazione Agraria" of Florence, which is a branch of the Technical Institute, and is under the direction of Prof. Bechi, experiments are made on the culture and diseases of the vine, the olive, and other plants, and analyses are made of soil, minerals, water, wines, &c. Attached to the Stazione is an experimental farm six hectares in size, and also a Government depot of agricultural machinery.

There is also in Florence a Bureau of Agricultural Entomology, under Prof. Tragioni-Tozzetti, where great attention is paid to the Phylloxera. This Bureau is in fact the centre of information for the whole of Italy on entomological subjects.

For practical instruction the province contains the Regio Istituto Forestale (Vallombrosa), the Regia Scuola di Pomologia e d'Orticoltura (Florence), and the Scuole Agrarie of Castaletti, near Signa, and of Scandicci, in the immediate neighbourhood of Florence. The Forest Institute of Vallombrosa, now under the Presidency of Prof. Piccioli, who is assisted by eight professors, was founded in 1869, on the model of the forestry schools of France, Germany, and Austria, to supply a sufficient number of trained officers for the Department of Woods and Forests. From 1869 till the present time, 159 students have entered the school, and of these 136 have received diplomas. All of these have entered into the service of their native country, except one who was a Swiss. The course of study lasts three years, during which time instruction is given in forestry and kindred subjects, and in French and German. The limits of age at entrance are sixteen and twenty-two, and the annual charge for board, residence, and instruction is fixed at 700 lire. The State pays a portion of the cost of some of the students, and sometimes their respective provinces do so.

Attached to the Institute is a library of works on forestry, and also the requisite collections and instruments, both chemical and scientific. A nursery which contains nearly 450,000 plants, and which can supply annually nearly 100,000 plants of from three to five years old, is also annexed. There is also a small fish-breeding establishment, in which about 10,000 trout-fry are annually hatched, and placed in the neighbouring streams.

The Royal School of Pomology and of Horticulture was established in 1882, and is now under the direction of Prof. Valvassori. Its object is to train vegetable and fruit gardeners. The course lasts three years, and is both theoretical and practical. The age for the admission of pupils is from fourteen to seventeen, preference being given to the sons of the smaller farmers, and the charges are 25 lire per month, besides 20 lire for the purchase of gardening-tools, &c., and an entrance fee of 10 lire. There are five professors, with a censor and two gardeners, and at present the number of pupils is thirty-two. For practical instruction the school possesses an orchard, and kitchen and flower gardens.

The Agricultural Institute of Castaletti has been in existence since 1859, when it was founded by Commendatore Leopoldo Cattani-Cavalcanti. It is now under the direction of Signor Riccardi-Manelli. One section of the school was placed on the footing of a Government technical institute during the life-time of the founder; but this has now been changed by the present Director, because the school has for its object, not the production of engineers and surveyors, but of factors or agents and head gardeners. The course of instruction in this institution lasts for four years, and the age of admission is from eleven to fifteen. Of late the charges have been increased, and in consequence the number of students has fallen from seventy to fifty. The entrance fee is now 50 lire; board, lodging, &c., 165 lire for the first and second years, and 180 lire for the third and fourth years; and 8 lire in addition per month for washing. The institution is not self-supporting.

The Agricultural School of Scandicci was founded as recently as 1884 by Count Napoleone Passerini for charitable purposes, his own villa being given up to the work. It was first only a day-school, but this year boarders have been admitted, and there are now ten boarders and eight externs. The object of the institution is to make good managers of rural estates. The course of study lasts for three years; the ages of admission are from fifteen to eighteen; the entrance fee is 10 lire, boarders paying in addition 36 lire per month, and 2 extra for washing. There are in all seven professors and masters. There is an experimental farm of 100 hectares in extent attached to the school, and a good library, and zoological, mineral, and agricultural collections, a chemical laboratory, an apiary, and a pigeon-house. A meteorological observatory of the second class, affiliated to the Central Observatory at Rome, is also annexed. The diplomas awarded to the pupils at the close of their course of study are countersigned by a special delegate of the Government.

According to the Report recently presented to the Foreign Office by Sir E. Malet on agricultural education in Prussia, the State annually gives £49,625 for agricultural instruction in that country, and £38,401 to the veterinary Colleges. Out of the former grant are supported the two Agricultural Colleges of Berlin and Poppelsdorf, the Pomological Institutes of Proskau and Geisenheim, and a station near Wiesbaden for experiments in agricultural chemistry; and subsidies are given to various provincial schools which are supported by local Boards but inspected by the central executive of the province. At the two Colleges the education is mainly scientific and theoretical, the ordinary course consisting of two terms of six months each. At the end of each term the subjects of examination are the science of farming and planting, farm management, physics and chemistry, botany, zoology, animal physiology, mineralogy, and geology. On passing these examinations the students are entitled to diplomas of proficiency in agricultural science. Those who wish to become land surveyors can proceed to a further course of two terms of six months each, in which the instruction given is of a most advanced kind, embracing mathematics, trigonometrical surveying, levelling, engineering, forestry, and plantation, the science of breeding and rearing cattle, dairy farming, mechanics and agricultural machinery, besides a course of law bearing on questions with which land surveyors have to do. According to the most recent report, the Berlin Agricultural College was attended by 98 students in the summer term, 12 of whom proceeded to the more advanced course, and in the winter term by 155 students, 27 of whom went in for the higher course. Poppelsdorf College was attended by 76 in the summer term, of whom 45 went on to the higher course, and in the winter term by 87, of whom 57 attended the larger course. With regard to the lower-grade schools receiving help from the grant in aid of agricultural education, 16 are intermediate schools which get £13,365 every year from the State. The school money varies from £3 5*s.* to £1 10*s.* per term of six months, and the subjects taught in these institutions comprise chemistry, mineralogy, physics, zoology, veterinary science, and farming. There are also numerous local winter elementary schools which supplement by theoretical training the practical teaching which the pupils have had in the fields in spring and autumn. £6648 is annually given to them.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—An examination will be held at Cavendish College on Tuesday, July 24, and following days, according to the results of which it is intended to award eight Scholarships of £30 a year, provided that candidates of sufficient merit present themselves. Candidates must be under eighteen years of age on October 1, 1888, and may offer for examination one or more of the following subjects: Classics, Mathematics, Natural Science, Modern Languages. The Scholars elected will be required to come into residence at Cavendish College in October 1888, and commence study for a Tripos or the Engineering course. Medical students may conveniently combine their medical work with the course for the Natural Science Tripos. It is also intended to offer in June 1889 three Scholarships of £30 to be competed for by students of the College who will then have resided not longer than one year. The College fee for board, lodging, and tuition, is £25 for each of the three University terms, and £15 for residence (optional) in the Long Vacation. For further information apply to the Bursar, Cavendish College, Cambridge.

In the paragraph last week about Prof. Darwin's lectures (p. 117), for "tin" read "sun."

SCIENTIFIC SERIALS.

Bulletin de la Société des Naturalistes de Moscou, 1887, No. 4 —On organic compounds in their relations to haloid salts of aluminium, by G. Gustafson (in German). In this second part the following conclusions are arrived at. The organic compounds undergo deep modifications in presence of the above salts. The reactions of addition are the chief ones, but the most interesting are those undergone by the aromatic hydrocarbons under the influence of chloride and bromide of aluminium; although most unstable, and therefore sometimes viewed as mere molecular compounds, they show a deep modification of the hydrocarbons from which they issue. They explain also the *rôle* of salts in organisms.—On the regeneration of lost organs in spiders, by V. Wagner (in French). This is the result of a double simultaneous process; the atrophy of the tissues belonging to the lost member, and the growth of the new one in the atrophied remnants of the old member. Both processes are described and illustrated.—Short notes on some (eighteen) Russian species of the genus *Blaps*, by E. Ballion (in German). —On two new Branchiopods from the Transcaspian region (*Apus haeckelii*, n. sp., and *Artemia asiatica*, n. sp.), by Dr. A. Walter.—Enumeration of the vascular plants of the Caucasus, by M. Smirnow (continued). The Ranunculaceæ are described; they contain ninety-eight species, belonging to seventeen genera, and out of them thirty-seven belong to the genus *Ranunculus*, and thirteen to that of *Delphinium*. The *Myosurus*, *Garidella*, *Caltha*, and *Actæa* number only one species each. The total number of Caucasian Phanerogams, according to Ledebour's "Flora Rossica," is 2965; now it must be estimated at about 4000 species. Out of the ninety-eight species of Ranunculaceæ described, forty belong exclusively to the flora of the East, while fifty-two are met with in South Russia, thirty in the Crimea, thirty-three in the Altai, twenty-four around Lake Baikal, and only twenty-one in the Urals, and eighteen in North Russia. Very interesting remarks follow as to the distribution of the Ranunculaceæ in separate parts of the Caucasus.

1888, No. 1.—Some remarks on the consequences of the earthquake of February 1887 in the Riviera, by H. Trautschold.—The chief noxious insects on tobacco in Bessarabia, an elaborate research by Prof. K. Lindeman. (Both papers in German.)—Count Alexis Razumovsky, first President of the Society, by Dr. Benzengre (in French).—List of plants of Tambof, by D. Litvinoff (continued).—On the hairs called auditive of the spiders, by W. Wagner (*Gehör-Organe* of Dahl). They belong to different types, and none of them can be recognized as performing the auditive function; they seem merely to be tactile organs of a higher structure.—Studies on the palæontological history of the *Ungulatæ*, by Marie Pavloff (second memoir). After having discussed the genealogy of the horse as viewed by V. Kovalevsky, Messrs. Marsh, Cope, Lydekker, Branco, and Schlosser, and discussed the rich material which Mrs. Pavloff was in possession of, the writer arrives at the following scheme. The eldest ancestors of the horse, *Phenacodus*, are found in the Eocene of North America; in Europe they are represented by the *Hyracotherium leporinum*, which, together with the *Pachynolophus* and *Anchilophus*, inhabited both continents. In the Miocene we find the *Anchitherium*, in America first, and later on in Europe; it was transformed in America into the *Protohippus* of the Mio-Pliocene. This last gave rise to the *Hippidium* and *Equus*, which largely developed during the Pliocene period in America (*E. parvulus*), Asia (*E. nomadicus*), Europe and Africa, where the *E. stenonis* was the ancestor of the Post-Pliocene *Equus caballus*. In how far our present horse originates from this later will be discussed next. Two plates illustrate the paper, written in French.

The *Memoirs of the Odessa Society of Naturalists* (vols. xi. and xii.) contain the usual quantity of elaborate work, especially in anatomy and physiology. The papers on the embryogeny of the fresh-water lobster, by M. Morin; on the embryogeny of the Caucasian scorpion *Androctonus ornatus*, by MM. A. Kovalevsky and Shulghin; on the development of the *Urospora mirabilis*, by M. Woltke; on the embryology of the *Mysis chameleo*, by M. Nusbaum; and on the morphology of the *Haplotrichum roseum*, by M. Khmielevsky, are elaborate articles profusely illustrated by excellent plates.—M. Krasilschik's researches on the structure and life of the *Cercobodo laciniægerens*—a new genus of the Flagellatæ—are most interesting, showing how this microscopic organism preys on Bacteria and digests them, and how complicated is its organization altogether.—The same author contributes an interesting paper on the parasite Fungi of insects, and M. Khawkin has an article on the buccal apparatus of the *Euglenæ* and *Astasiæ*, as also on the laws of heredity in the case of unicellular organisms; and Dr. Kultchitsky studies the intestinal canals of several fishes.—Geology and mineralogy are represented by R. Prendel's article on the Wiluite, from which it appears that the crystals of this interesting mineral have a double composition—those parts of it which penetrate into the depth of the crystal as cones set upon the surfaces of the pyramids differing both by their density and refractive power from the parts which are built upon the faces of the prisms; three papers by Prof. Sintsoff on the water-bearing deposits of Kishineff, the Steppe deposits on the left bank of the Lower Volga, and the Pliocene of South Russia; and on the crystalline rocks of Crimea, by M. Prendel.—Prof. Klossovsky contributes a paper on the oscillations of temperature and density of the water of the Black Sea in the neighbourhoods of Odessa; and Mrs. Mary Balashoff has an article on the influence of small ponds and of limited supplies of water on the development of *Planorbis*.—Chemistry is represented by one paper, on the laws of dissolution of salts, by R. Umoff.

SOCIETIES AND ACADEMIES.

London.

Royal Society, April 26.—"On the Occurrence of Aluminium in Certain Vascular Cryptogams." By A. H. Church, M.A., F.C.S. Communicated by Dr. J. H. Gilbert, F.R.S.

Most of the older and more complete analyses of plant-ashes disclosed the presence of sensible quantities of alumina. But of late years this substance has been regarded as accidental, and has been excluded from ash-constituents with the single exception of certain species of *Lycopodium*. Since 1851 several analysts have proved the presence of large quantities of alumina in the ashes of these plants The author has confirmed and extended their results, and has shown that the allied genus *Selaginella* does not absorb alumina. He found, however, two species of *Lycopodium*—namely, *L. Phlegmaria* and *L. billardieri*—from which this constituent is absent. The anomaly was explained by the epiphytic nature of these plants, which have no direct access to the soil. The author has further examined certain species belonging to genera nearly related to *Lycopodium*, such as *Equisetum*, *Ophioglossum*, *Salvinia*, *Marsilea*, and *Psilotum*, in all cases with negative results. But he has found 20 per cent. of alumina in the ash of a New Zealand tree-fern, and has also discovered abundance of this substance in *Cyathea medullaris* and *Alsophila australis*, and more than mere traces in *Dicksonia squarrosa*. The last part of the paper is occupied with some considerations having reference to the connection between elementary plant-food and the periodic law.

May 17.—"On the Electromotive Properties of the Leaf of *Dionæa* in the Excited and Unexcited States." No. II. By J. Burdon-Sanderson, M.A., M.D., F.R.S., Professor of Physiology in the University of Oxford.

The author has continued his experimental inquiries, of which the results were communicated to the Royal Society under the same title in 1881. In the introduction to the paper he gives a summary of his previous observations, which led to the conclusion that the property by virtue of which the excitable structures of the leaf respond to stimulation, is of the same nature with that possessed by the similarly-endowed structures of animals. He then proceeds to state that the main purpose of his subsequent investigations has been to determine the relation between two sets of phenomena which might, in accordance with the language commonly used in animal physiology, be termed respectively those of the "resting current" and of the "action current" of the leaf, *i.e.* between the electrical properties possessed by the leaf when stimulated, and those which it displays when at rest. Assuming the excitatory response in the leaf to be of the same nature as the excitatory variation or "action current" in muscle and nerve, the question has to be answered, whether in the leaf the response is a sudden diminution of a previously existing electromotive action (according to the pre-existence theory of du Bois-Reymond), or the setting up at the moment of stimulation of a new electromotive action—in short, whether and in how far the two sets of phenomena are inter-dependent or the contrary.

An observation recorded in his former paper suggested proper methods. It had been shown that by passing a weak voltaic current through the leaf for a short period in a particular direction, its electromotive properties could be permanently *modified* without loss of its excitability. If it could be shown that the influence of this modification extended to both orders of phenomena, those of rest and excitation, and that both underwent corresponding changes of character under similar conditions, this would go far to prove that an essential relation existed between them.

Acting on this suggestion, the author has had recourse to modes of experiment similar to those which have been employed during the last few years in the investigation of the newly-discovered "secondary electromotive" phenomena of muscle and nerve (see "Oxford Biological Memoirs," vol. i. part 2). The details of these experiments, made in 1885, are given in the first three sections of the paper. They relate to (1) the more immediate effect of the current as seen in the records of successive galvanometric observations made at regular intervals; (2) the more permanent influence of the current on the electromotive properties of the unexcited leaf, and on its electrical resistance; and (3) the concomitant modification of its behaviour when stimulated.

The general result of these experiments is to show that the two orders of phenomena, the excitatory and those which relate to the resting state, are so linked together that every change in the state of the leaf when at rest conditionates a corresponding change in the way in which it reacts to stimulation—the correspondence consisting in this, that the direction of the response is opposed to that of the previous difference of potential between the opposite surfaces, so that as the latter changes from ascending to descending, the former changes from descending to ascending.

The author considers that this can only be understood to mean that the constantly operative electromotive forces which find their expression in the persistent difference of potential between the opposite surfaces, and those more transitory ones which are called into momentary existence by touching the sensitive filaments or by other modes of stimulation, have the same seat, and that the opposition between them is in accordance with a principle applicable in common to the excitable structures of plants and animals, viz. that the *property which renders a structure capable of undergoing excitatory change is expressed by relative positivity, the condition of discharge by relative negativity*.

The fourth section of the paper is devoted to an investigation made in 1887, of the events of the first second after excitation, made with the aid of a pendulum-rheotome specially adapted for the purpose. The fifth contains the description of the records obtained by photographing the electrical phenomena of the excitatory reaction, as observed with the aid of the capillary electrometer, on rapidly-moving plates. Both of these series of observations serve to confirm and complete the results obtained by other methods. The photographs were exhibited.

Physical Society, May 12.—Prof. Reinold, F.R.S., President, in the chair.—The following papers were read:—Note on the condition of self-excitation in a dynamo machine, by Prof. S. P. Thompson. It is a well-known fact that a series dynamo running at a given speed will not excite itself unless the resistance is less than a certain value, depending on the speed and construction of the machine, and if the resistance is slightly less than this critical value the excitation will not be such as to saturate the magnets. According to the primitive statement of the action of self-exciting dynamos on the "compound interest law," a dynamo should excite itself to saturation at any finite speed providing the resistance is not infinite. An explanation of the observed facts is given in the paper, without any assumption as to the curve of magnetization. If $E =$ E.M.F. of the machine, $n =$ speed, $C =$ number of wires on outside of armature, $N =$ number of magnetic lines, $i =$ current, $S =$ number of turns on magnet, ΣR and $\Sigma \rho$ the sums of the electric and magnetic resistances respectively, then $E = nCN$, $i = nCN/\Sigma R$, and $N = 4\pi Si/\Sigma\rho$. From these it is easily seen that $4\pi nCS = \Sigma\rho \cdot \Sigma R$, (A).; *i.e.* for a dynamo running at constant speed the product of the magnetic and electric resistances is constant, and the dynamo will not excite itself if ΣR is greater than $4\pi nCS/\Sigma\rho$. Similarly for a given value of ΣR, excitation is impossible if n is less than $\Sigma\rho \cdot \Sigma R/4\pi CS$. For a value of ΣR less than the critical value the excitation increases until the magnetic resistance is increased so that equation (A) is satisfied. The corresponding formula for shunt machines is $4\pi nCZ = \Sigma\rho\left\{(r_a + r_s) + \frac{r_a r_s}{R}\right\}$; where $Z =$ number of shunt turns; r_a, r_s, and R, the resistances of armature, shunt, and external circuits respectively. In the discussion which followed, Mr. Kapp descibed a method used in testing dynamos, for determining the minimum speed at which dynamos will excite themselves, and from thence determining the magnetic resistance of the air gap. In all cases experiment showed this to be less than the calculated resistance, generally in the proportion of 1500 to 1860, the difference being greater in low-tension machines. Prof. Ayrton pointed out that permanent magnetism was not taken into account, and that the apparent resistance due to self-induction, and between the brushes and commutator were considerable for small currents. Lord Rayleigh and Sir W. Thomson had shown critical speeds for given resistances to exist in Faraday's disk dynamo. He (Lord Rayleigh) did not approve of the term "magnetic resistance," and thought "reluctance," as recently suggested by Mr. Heaviside, would be preferable.—Note on the conditions of self-regulation in a constant potential dynamo machine, by the same author. In "Dynamo-Electric Machinery" a formula $\frac{Z}{S} = \frac{r_s}{r_a + r_m}$ is given as expressing the ratio of the number of turns in the shunt and series windings of a compound dynamo. This is on the assumption that there is no saturation within the working limits. As this assumption is not legitimate, a correcting factor is necessary. The factor is shown to be the ratio of the average permeability over the whole working range to the permeability corresponding with no external current. The formula is transformed so as to be expressed in terms of the "satural" data of the machine, which, as shown in a previous paper, can be calculated from its details.—On magnetic lag, and the work lost due to magnetic lag in alternating current transformers, by Mr. Thomas H. Blakesley. The method adopted to detect the lag is to place dynamometers in both circuits, and one with a coil in each. Then, on the supposition that the E.M.F. of the secondary circuit is entirely due to the changing magnetism of the core, the author proves that the tangent of the magnetic lag angle must be equal to $\dfrac{\frac{m}{n}C\alpha_3 - B\alpha_2}{\frac{m}{n}\sqrt{(AB\alpha_1\alpha_2 - C^2\alpha_3^2)}}$; where m and n are the number of turns in the primary and secondary coils respectively; A, B, C, the constants of the dynamometers; and α_1, α_2, α_3, their angular reading. A is such that $A\alpha_1 = \frac{I_1^2}{2}$, where I_1 is the maximum value of the primary current. A table of actual results is given, where the magnetic lag is about $5\frac{1}{4}°$. The whole power given out by the machine takes the form $r_1 A\alpha_1 + r_2 \frac{m}{n} Cd_2$, where r_1 and r_2 are the resistances of the primary and secondary circuits, while the power lost in hysteresis is expressed by $r_2\left(\frac{m}{n}C\alpha_3 - B\alpha_2\right)$. The lag is attributed to an induced magnetic stress called into being by the increasing or decreasing magnetism itself, and always opposing it as motion in a medium induces an opposing force of friction. By supposing such an induced magnetic stress in quadrature (as Mr. Blakesley expresses it) with the magnetism, and of such a value as when compounded with the stresses due to the currents shall bring the resultant into quadrature with the secondary current, the effective magnetic stress is obtained. This involves a new idea called magnetic self-induction with its coefficient. The whole problem is treated by the geometrical method, which the author has applied to several other problems in alternating currents. Mr. Kapp, Profs. Thompson, Perry, and Ayrton, and Lord Rayleigh took part in discussing the paper.—On a simple apparatus for the measurement of the coefficient of expansion by heat, by Prof. W. E. Ayrton, F.R.S., and Prof. J. Perry, F.R.S. The apparatus consists of a metal tube, within which the wire or rod whose coefficient is to be determined is placed. One end of the wire is rigidly attached to one end of the tube, and the other end connected to an Ayrton and Perry magnifying spring, a pointer attached to which indicates the change of length due to alteration of temperature. Steam or water may be passed through the tube, the temperature of the wire being shown on a thermometer. The arrangement is very sensitive, and with a pointer about 20 cm. long, the motion is magnified about 1000 times.—A magnifying spring attached to an aneroid was also shown, and its great sensibility demonstrated. A combination of a spring of large diameter and pitch with one of small diameter and pitch was exhibited. By such a combination small rotations can be immensely magnified. The great features of the patent spring as a magnifier are the entire absence of friction and back lash, and the large range of proportionality.

Chemical Society, May 17.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—Researches on the constitution of azo- and diazo-derivatives; (iv.) diazo-amido-compounds, by Prof. Meldola, F.R.S., and Mr. F. W. Streatfield.—The colour of some carbon compounds, by Prof. Carnelly, and Mr. J. Alexander. An investigation of a number of metallic derivatives of ortho- and para-nitrophenol has given the following results: (1) in all cases without exception the colour passes towards the red end of the spectrum as the temperature rises; (2) the colour of the ortho-derivative is nearer the red end than that of the corresponding para-compound; (3) a comparison of the nitrophenates of the metals belonging to the same sub-group shows that the colour passes towards the red end as the atomic weight of the metal increases; (4) when the same salt occurs in both the anhydrous and the hydrated state, the colour passes towards the red end as the quantity of water of crystallization diminishes; (5) as regards the salts investigated, the para-compound always takes up a larger quantity of water of crystallization than the corresponding ortho-compound. In the course of the discussion which followed the reading of the paper, Prof. Armstrong, F.R.S., remarked that the facts advanced were far too few to justify the very general conclusions arrived at by the authors; all who had worked with the nitrophenols were well aware that the colour changed on heating in the manner described; and there was no novelty in the statement that the para-nitrophenols crystallized with the larger proportion of water. Referring to the authors' fourth deduction, he quoted calcium parachlorodiorthonitrophenate as an exception, since this compound can be obtained either in yellow anhydrous crystals, or in deep-orange hydrated crystals.—The identity of natural and artificial salicylic acid, by Prof. Hartley, F.R.S. Spectroscopic examination of the two compounds establishes their identity.—Researches on the relation between the molecular structure of carbon compounds and their absorption spectra (part viii.), by the same.—A definition of the term atomic weight and its reference to the periodic law, by the same. The author is of opinion that the fact that the atomic weights are real measures of the quantity of matter in the atoms of the elements is often overlooked, and advocates the adoption of the definition: The atomic weight of an element is the ratio of the mass of its atom to the mass of an atom of hydrogen. The periodic law then admits of being stated thus: The properties of the atoms are a periodic function of their masses.

Geological Society, May 23.—Dr. W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—On the spheroid-bearing granite of Mullaghderg, Co. Donegal, by Dr. Frederick H. Hatch. Communicated with the permission of the Director-General of the Geological Survey. This paper deals with a remarkable variety of granite which may be compared with the well-known orbicular diorite or Napoleonite of Corsica. According to Mr. J. R. Kilroe, of the Geological Survey of Ireland, who first discovered this interesting rock, the concretionary balls occur in close juxtaposition in a mass of granite of 5 or 6 cubic yards in size. They have not been found in any other portion of the granite area. The author gave a detailed description of the microscopic structure of the normal granite. He also described the spheroidal bodies, and gave a synopsis of the literature concerning the occurrence of similar concretionary bodies in granite. The conclusion arrived at was, that concretionary bodies occurring in granite may, according to the mode of arrangement of their constituents, be divided into three classes, viz. (1) the *concretionary patches* of Phillips; (2) the *granospherites* of Vogelsang; (3) the *belonospherites* of Vogelsang. The spheroids from Mullaghderg belong to the last-mentioned class. They must be regarded as concretions formed, during the consolidation of the granite magma, by a process of zonal and radial crystallization around an earlier-formed nucleus. Remarks on this paper were offered by Mr. Rutley, Prof. Bonney, Dr. Hicks, and Prof. Judd.—On the skeleton of a Sauropterygian from the Oxford Clay near Bedford, by R. Lydekker.—On the Eozoic and Palæozoic rocks of the Atlantic coast of Canada in comparison with those of Western Europe and the interior of America, by Sir J. W. Dawson, F.R.S. The author referred to the fact that since 1845 he had contributed to the Proceedings of the Geological Society a number of papers on the geology of the eastern maritime provinces of Canada, and it seemed useful to sum up the geology of the older formations and make such corrections and comparisons as seemed warranted by the new facts obtained by himself, and by other observers of whom mention is made in the paper. With reference to the Laurentian, he maintained its claim to be regarded as a regularly stratified system probably divisible into two or three series, and characterized in its middle or upper portion by the accumulation of organic limestone, carbonaceous beds, and iron-ores on a vast scale. He also mentioned the almost universal prevalence in the northern hemisphere of the great plications of the crust which terminated this period, and which necessarily separate it from all succeeding deposits. He next detailed its special development on the coast of the Atlantic, and the similarity of this with that found in Great Britain and elsewhere in the west of Europe. The Huronian he defined as a littoral series of deposits skirting the shores of the old Laurentian uplifts, and referred to some rocks which may be regarded as more oceanic equivalents. Its characters in Newfoundland, Cape Breton, and New Brunswick were referred to, and compared with the Pebidian, &c., in England. The questions as to an upper member of the Huronian or an intermediate series, the Basal Cambrian of Matthew in New Brunswick, were discussed. The very complete series of Cambrian rocks now recognized on the coast-region of Canada was noticed, in connection with its equivalency in details to the Cambrian of Britain and of Scandinavia, and the peculiar geographical conditions implied in the absence of the Lower Cambrian over a large area of interior America. In the Ordovician age a marginal and a submarginal area existed on the east coast of America. The former is represented largely by bedded igneous rocks, the latter by the remarkable series named by Logan the Quebec Group, which was noticed in detail in connection with its equivalents further west, and also in Europe. The Silurian, Devonian, and Carboniferous were then treated of, and detailed evidence shown as to their conformity to the types of Western Europe rather than to those of America. In conclusion, it was pointed out that though the great systems of formations can be recognized throughout the northern hemisphere, their divisions must differ in the maritime and inland regions, and that hard and fast lines should not be drawn at the confines of systems, nor widely different formations of the same age reduced to an arbitrary uniformity of classification not sanctioned by Nature. It was also inferred that the evidence pointed to a permanent continuance of the Atlantic basin, though with great changes of its boundaries, and to a remarkable parallelism of the formations deposited on its eastern and western sides. The President, whilst recognizing the importance of the paper, doubted whether the question of correlation of the Pre-Cambrian rocks on either side of the Atlantic was ripe for discussion. Dr. Hicks agreed with most of the conclusions of the author, including the correlation of the Huronian with the Pebidian. Some observations on the paper were also made by Dr. Scott, Dr. Hinde, and Mr. Marr.—On a hornblende-biotite rock from Dusky Sound, New Zealand, by Captain F. W. Hutton.

Zoological Society, May 15.—Dr. A. Günther, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of April 1888; and called special attention to two Rock-hopper Penguins from the Auckland Islands, presented by Capt. Sutcliff, R.M.S.S. *Aorangi*, on April 19; also to two Indian Hill-Foxes, and to a fine example of the Spotted Hawk-Eagle (*Spizaëtus nipalensis*), presented by Colonel Alex. A. A. Kinloch, and received on April 20.—A communication was read from Mr. George A. Treadwell, containing an account of a fatal case of poisoning from the bite of the Gila Monster (*Heloderma suspectum*).—Mr. Boulenger exhibited the type-specimen of a singular new genus of Snakes (*Azemiops feæ*) recently discovered by M. Fea, of the Museo Civico of Genoa, in the Kakhim Hills, Upper Burma. Mr. Boulenger proposed to refer this genus provisionally to the family Elapidæ.—The Secretary read a letter addressed to him by Mr. E. C. Cotes, Entomological Department, Indian Museum, Calcutta, respecting the insect-pests of India, and requesting the assistance of entomologists in working out the species to which they belong.—Mr. H. Seebohm exhibited and made remarks on a series of specimens of Pheasants from Mongolia, Tibet, and China, including examples of the two species discovered by Colonel Prjevalski, *Phasianus strauchi* and *P. vlangali*.—Prof. F. Jeffrey Bell exhibited and made remarks on three specimens of a large Pennatulid (*Funiculina quadrangularis*) obtained by Mr. John Murray on the west coast of Scotland. They showed very clearly the differences between examples of this species of different ages.—Mr. R. Bowdler Sharpe gave an account of a third collection of birds made by Mr. L. Wray in the main range of mountains of the Malay Peninsula, Perak. The present paper contained descriptions of ten species new to science, amongst which was a new *Pericrocotus*, proposed to be called *P. wrayi*.—Prof. F. Jeffrey Bell read the descriptions of four new species of Ophiuroids from various localities.—Mr. F. E. Beddard read a paper containing remarks on certain points in the visceral anatomy of *Balæniceps rex* bearing upon its affinities, which he considered to be with the Ardeidæ rather than with the Ciconiidæ. Mr. G. B. Sowerby gave the description of a gigantic new species of Mollusk of the genus *Aspergillum* from Japan, which he proposed to name *A. giganteum*.

Institution of Civil Engineers, May 29.—Annual General Meeting.—Mr. George B. Bruce, President, in the chair.—After the reading of the Report, hearty votes of thanks were passed to the President, to the Vice-Presidents, and other members of the Council, to the Auditors, to the Secretaries and staff, and to the Scrutineers.—The ballot for the Council resulted in the election of Mr. G. B. Bruce, as President; of Sir John Coode, Mr. G. Berkley, Mr. H. Hayter, and Mr. A. Giles, M.P., as Vice-Presidents; and of Mr. W. Anderson, Mr. B. Baker, Mr. J. W. Barry, Sir Henry Bessemer, F.R.S., Mr. E. A. Cowper, Sir James N. Douglass, F.R.S., Sir Douglas Fox, Mr. C. Hawksley, Mr. J. Mansergh, Mr. W. H. Preece, F.R.S., Sir Robert Rawlinson, K.C.B., Sir E. J. Reed, K.C.B., F.R.S., M.P., Mr. W. Shelford, Mr. F. C. Stileman, and Sir William Thomson, F.R.S., as other members of the Council.—The Council has made the following awards to the authors of some of the papers read and discussed at the ordinary meetings during the past session, or printed in the minutes of proceedings without being discussed, as well as for papers read at the supplemental meetings of students :—For papers read and discussed at the ordinary meetings: a Telford Medal and a Telford Premium to Robert Abbott Hadfield, for "Manganese in its Application to Metallurgy," and "Some Newly-discovered Properties of Iron and Manganese"; a Watt Medal and a Telford Premium to Peter William Willans, for "Economy-Trials of a Non-condensing Steam-Engine, Simple, Compound, and Triple"; a Telford Medal and a Telford Premium to Dr. Edward Hopkinson, for "Electrical Tramways—the Bessbrook and Newry Tramway"; a Watt Medal and a Telford Premium to Edward Bayzand Ellington, for "The Distribution of Hydraulic Power in London"; a Telford Medal and a Telford Premium to Josiah Pierce, Jun., for "The Economic Use of the Plane-Table in Topographical Surveying"; a George Stephenson Medal and a Telford Premium to Sir Bradford Leslie, K.C.I.E., for "The Erection of the 'Jubilee' Bridge, carrying the East Indian Railway across the River Hooghly at Hooghly"; and the Manby Premium to the late Hamilton Goodall, for "The Use and Testing of Open-hearth Steel for Boiler-making." For papers printed in the Proceedings without being discussed: a Watt Medal and a Telford Premium to Prof. Victor Auguste Ernest Dwelshauvers-Dèry, for "A New Method of Investigation applied to the Action of Steam-Engine Governors"; and Telford Premiums to William Mann Thompson, for "Improved Systems of Chaining for Land and Engineering Surveys"; to James William Wyatt, for "Sizing Paper with Rosin"; and to Dugald Drummond, for "The Heating of Carriages by Exhaust Steam on the Caledonian Railway." For papers read at the supplemental meetings of students the following Miller Prizes have been given: to David Sing Capper, for "The Speed-Trials of the latest addition to the *Admiral* Class of British War-Vessels"; to Lawrence Gibbs, for "Pumping-Machinery in the Fenland and by the Trentside"; to Harold Medway Martin, for "Arched Ribs and Voussoir Arches"; to John Henry Parkin, for "River-Gauging at the Vyrnwy Reservoir"; to Alfred Chatterton, for "The Prevention and Extinction of Fires"; to John Holliday, for "Boiler Experiments and Fuel-Economy"; to Arthur Wharton Metcalfe, for "The Classification of Continous Railway-Brakes"; to Robert Jarratt Money, for "Railway Engineering in British North America."

Victoria Institute, June 4.—The annual general meeting was held at the house of the Society of Arts. The President, Prof. G. G. Stokes, P.R.S., M.P., took the chair. The twenty-second Annual Report was read by Captain Frank Petrie, the Honorary Secretary, and Sir Monier-Williams delivered an address on mystical Buddhism. A vote of thanks was accorded to the President.

Paris.

Academy of Sciences, May 28.—M. Janssen, President, in the chair.—New theory of equatorials (continued), by MM. Lœwy and Puiseux. In order to verify the already explained theory, the authors here compare the values of the constants obtained by physical processes with those resulting from the astronomical methods based on the observation of transits or on the apparent variations of the right ascensions or declinations. They conclude with some general remarks on the employment of the equatorial *coudé*.—On the measurement of low temperatures, by MM. L. Cailletet and E. Colardeau. The researches here described have been undertaken for the purpose of obviating the difficulties hitherto felt in employing hydrogen thermometers for the measurement of low temperatures.—Researches on ruthenium, by MM. H. Debray and A. Joly. These studies are occupied chiefly with the rutheniates of potassa and silver, and the heptarutheniates of potassa and soda. The authors find that, although there exists an evident analogy in the composition and reactions of the rutheniate and heptarutheniate of potassa on the one hand, and the manganate and permanganate of potassa on the other, no relation of isomorphism has been detected between the salts of the acids of ruthenium and those of manganese. The rutheniate of potassa is hydrated, while the manganate, like the sulphate, is anhydrous.—On the monthly charts of the North Atlantic currents, by M. Simart. Continuing the work of Commander Brault, the author has prepared two series of charts (diagrams and results) based on 60,400 observations obtained from the records of the French Admiralty and various other sources. The charts of results give the currents most likely to be met with from month to month all the year round, while the diagrams indicate the currents that may possibly be met, especially near the coasts, where they present the greatest dangers to seafarers.—Origin of the aurora borealis, by M. Jean Luvini. This phenomenon is regarded as analogous to the discharge of electricity in thunderstorms, the only difference consisting in their different degrees of intensity. Both are attributed to the friction of particles of water and ice and occasionally of other minute bodies drawn by the aërial currents into the higher atmospheric regions and disseminated over the terrestrial atmosphere some hundred miles thick. The northern lights are most frequent about the pole, where the air abounds most in icy particles and where the field of terrestrial magnetism is most intense.—Observations of the new planet Palisa (279) made at the Observatory of Algiers with the 0·50m. telescope, by MM. Rambaud and Sy. These observations, which include the positions of two comparison stars and the apparent positions of the planet, cover the period from May 18 to May 22.—Observations of the planet Borelly (278) made at the Observatory of Marseilles with the 0·26m. Eichens equatorial, by M. Esmiol. During these observations, continued from May 13 to May 21, the planet appeared to be of magnitude 11·5.—On the supernumerary arcs accompanying the rainbow, by M. Boitel. The position of these arcs, as determined by Airy on the principles of diffraction, and generally accepted as absolute, is shown to be merely a first approximation, which the author hopes soon to supplement by more accurate calculations.—Researches on the application of the rotatory power to the study of the compounds formed by the action of the neutral tungstates of soda and potassa on the solutions of tartaric acid, by M. D. Gernez. From these experiments it appears that the neutral tungstates of soda and potassa behave analogously in their action on tartaric acid.—On the sesquisulphide of rhodium, by M. E. Leidié. The author describes the methods of preparation of this substance and of the double sulphides both by the wet and dry processes.—On two isomerous naphthoquinoleins, by M. Alphonse Combes. The only terms hitherto known of these rare compounds are those obtained by Skraup by making glycerine act on the naphthylamines in the presence of sulphuric acid. The author here describes two new terms of the series, as well as a means by which several others may also be obtained.—On a new species of Coregonus, by M. Victor Fatio. To this species, discovered in the French Lake Bourget, the author has given the name of *Coregonus Bezola*. It is a well-defined local variety.—On the germination of *Anemone apennina*, by M. Ed. de Janczewski. This species presents in its germination a curious and most remarkable anomaly, differing in this respect from all other dicotyledonous plants.—On the bust of a woman carved in the root of an equine tooth, by M. Ed. Piette. This specimen of prehistoric art, recently discovered by the author in the cave of Mas d'Azil, Ariège, presents several points of interest to the anthropologist. Owing to the contracted space, the artist had to suppress shoulders and arms, merely suggesting the outlines of the sides. But the pendant breasts are well executed, and the profile of the face carefully delineated. The nose is large and rounded, the lips thick, the chin retreating like that of the Naulette jaw, but the forehead is high and not receding like that of the Neanderthal skull. It is the third extant representation of a woman of the Quaternary period, the two others being M. de Vibraye's "Venus" and the "Reindeer Woman," both from Laugerie-Basse.

Berlin.

Physical Society, May 18.—Prof. du Bois-Reymond, President, in the chair.—Dr. Dieterici gave an account of his experiments on the determination of the latent heat of evaporation of water at 0° C. Regnault's experiments on the latent heat of evaporation of water were made at higher temperatures, and had led to the construction of a formula according to which the latent heat of evaporation at 0° C. must be 607 units of heat. The speaker, using an ice-calorimeter, had made a direct determination of this value. A glass tube, with its lower end blown out into a bulb and filled with water, was immersed in the chamber of the calorimeter, the upper end of the tube being connected with an air-pump, and a small column of sulphuric acid being interposed between the pump and the tube. As soon as the apparatus had assumed a perfectly uniform temperature, a vacuum was produced by the air-pump, whereupon the water in the tube evaporated, taking up from the calorimeter the heat necessary for its evaporation. Values were obtained from a series of ten experiments, which differed from each other by not more than $\frac{3}{4}$ per cent. In order to meet the objection which might be raised—namely, that the temperature at which the evaporation took place was not 0° C.,—Dr. Dieterici repeated his experiments, using a platinum instead of a glass tube. The values obtained in this set of experiments only differed by ¼ per cent. The mean of the two sets of experiments was identical, and the final outcome of the whole research was that the latent heat of evaporation of water at 0° C. is 596·4 thermal units. The speaker then discussed fully the theoretical significance of the above results, and described an experiment he had made in order to determine the latent heat of evaporation of ice at 0° C. The method employed was the same as above, but it did not yield the value which was theoretically expected, which should have been equal to the sum of the latent heat of evaporation of water and of the latent heat of fusion of ice. The cause of the divergence was due to the fact that the ice used was not clear and crystalline, but milky and opaque. Dr. Dieterici intends to repeat these determinations next winter.—Prof. von Bezold gave an account of a paper which he had recently read before the Berlin Academy on the thermodynamics of the atmosphere. Recent meteorology has derived very considerable benefit from the application of thermodynamics to events taking place in the atmosphere; but up to the present time all the researches had only dealt with adiabatic and reversible processes. As a matter of fact, these processes are neither adiabatic nor reversible, since, when the air is cooled, its aqueous vapour is condensed, and the water thus formed falls as either rain, hail, or snow. If both these facts are taken into account, the calculations involved thereby become so complicated that Prof. von Bezold was only enabled to proceed to the application of thermodynamics to the processes which really take place in the atmosphere by employing an artifice; the latter consisted of the graphic method introduced by Clapeyron with such marked success as a technical method. For this purpose the consideration starts with the assumption that the air is dry, in which case the equation for its condition is given in terms of its volume, pressure, and temperature, and can be represented by plane co-ordinates. The variable amount of aqueous vapour in the air is then treated as a further variable in the third co-ordinate, in such a way that for any given amount of aqueous vapour in the air a new co-ordinate representing the change in condition of the air is obtained. When, on cooling, a portion of this aqueous vapour is condensed, the curve representing the change of condition passes over from one plane to the other, pursuing its further course in the latter plane. In this way it becomes possible, as the speaker fully showed, to treat non-reversible and pseudo-adiabatic processes theoretically, according to the laws of thermodynamics. It can thus be shown in the case of the Föhn and of cyclones, as well as of anti-cyclones, which are not reversible but reversed processes, that the theoretical considerations lead to results which are found to be confirmed by experience. Thus, according to theory, in an anticyclone occurring in winter, there should be a rise of temperature at some height above the earth, a fact which is now observed at all meteorological stations at high altitudes.

Physiological Society, May 25.—Prof. du Bois-Reymond, President, in the chair.—Dr. Weyl gave an account of the results of his further researches on silk. Among the products of decomposition of albumen and proteid substances, one is known as a snowy crystalline body, which is considered to be leucin, and is generally regarded as being also a product of the decomposition of silk. Since this substance may be obtained in large quantities by the decomposition of silk, the speaker had prepared it from this source and analyzed it, and has come to the conclusion that it is not leucin (amidocaproic acid), but rather another amidated acid—namely, alanin. Of the two possible isomers of alanin, it is α-alanin which is obtained by the decomposition of silk. Dr. Weyl laid stress on the fact that Schützenberger had also concluded that alanin and glycocol occur among the products of decomposition of silk, notwithstanding that, during his elaborate and careful researches on proteids, he employed a method which is as unfavourable as can be imagined for determining this point: this result is now confirmed by the speaker's researches. Schützenberger's further supposition, that an amido-acid of the acrylic series can be prepared from silk, was not supported by Dr. Weyl's analyses.—The same speaker further communicated the results of his researches on the physiological action of anthrarobin and chrysarobin, which have recently been largely used in medical practice. These two substances, whose chemical constitution and relationship to alizarin and anthracene have been made clear by Liebermann, are largely used as reducing-bodies, especially in skin diseases. Dr. Weyl endeavoured, by means of experiments on rabbits and dogs, and on himself, to determine the physi logical action of anthrarobin, and found that it possesses absolute no action on the living organism, even when taken by the mou in relatively large doses, or injected subcutaneously. It cou be detected in an unaltered condition in the urine, so that th substance, notwithstanding that it possesses a great affinity f oxygen, passes through the body without being oxidize Chrysarobin, on the other hand, has a very different action notwithstanding its close relationship to the non-injurio anthrarobin, it has a powerfully poisonous action, so that a experiments made with it were of necessity confined to rabbi and dogs. The speaker was unable to confirm the statemen of several authors that chrysarobin reappears in the urine chrysophanic acid. It is rather his opinion that chrysarobin first excreted in an unaltered condition, and only subsequentl undergoes a change into chrysophanic acid. It remains f further experiments to clear up this point.—Prof. Gad spoke o the phosporescent moss *Schistostega osmundacea*, which he ha been for some time cultivating, and which he exhibited. thorough investigation of the phosphorescent powers of this pla promises a rich harvest of facts from a physical point of view it is well known, on the basis of morphological research, that th phosphorescence is due to a reflection of the incident light.

In the report of the Berlin Meteorological Society, May (p. 119), the expression "a spring-vane," should have been " vane made of feathers."

THE BOYS' "YARRELL."

An Illustrated Manual of British Birds. By Howard Saunders, F.L.S., F.Z.S. Part I., April 1888. (London: Gurney and Jackson.)

A BOYS' "Yarrell" is a book that many ornithologists have long wished to see. More than six years ago a scheme for producing one was thought out, and Mr. Howard Saunders was invited, and consented, to aid in its production. *Dîs aliter visum*—the scheme fell through for the time; but now the proposed coadjutor has been favoured by fortune, and has by himself been able to put it into operation. He is to be heartily congratulated accordingly, and not only he, but scores if not hundreds of boys—to whom the work, just begun, will afford no less delight than good instruction.

From the moment when the first part of the original edition of Yarrell's "British Birds" appeared—now more than fifty years ago—it was seen that a new era in the study had dawned. The author had no other scientific training than that which, amid the turmoil of business, he had been able to acquire for and by himself; but he knew the value of scientific work, and having an uncommon amount of common-sense, he knew that the introduction of too much of it into his books would render them indigestible to the unscientific public of those days. Hence his "British Fishes" and "British Birds," though intentionally popular, are permeated by an only half-concealed thread of scientific thought, which, without its interfering with their readableness, the true aspirant could catch, and guide himself thereby to a higher level. From the publishers' point of view, these works were successful beyond expectation; but they had one great drawback. They were abundantly illustrated, and therefore necessarily expensive. This put them, and especially the "British Birds," to which the theme of the present notice relates, out of the reach of almost all but those in easy circumstances. Scarcely a school-boy, however much he might covet a copy, such as he might happen to see in some more favoured hands, could out of his pocket-money afford to buy a "Yarrell"; and even though the price of the later editions has been somewhat reduced, there is not one of them that would be within his means. Moreover, they contained a good deal more than he cared to know. The sort of information he wanted was, let us say, whether the bird he saw on the top of a hedge was a Cirl-Bunting or not; or whether, as the gamekeeper had told him, the Sparrow-Hawk was "that artful to turn hisself" into a Cuckoo in the spring; or, again, whether the bird that had suddenly risen as he walked along the brook-side was a Summer-Snipe or a Sandpiper, and what was the difference, if any, between them. Of course he would also like to know how the Wild Duck got her ducklings down into the water from the hollow tree in which he had found her nest, and what became of the Swallows in winter, and the Fieldfares in summer. Yarrell's work gave all this in the best way possible, but it added a great deal more that the school-boy did not care a button for. It told him of "orders" and "genera," and gave "characters"—which to him were as hard as Greek verbs. Every now and then there was a bit of anatomy; but that was to the good, for your inquiring school-boy rather likes making a rough dissection, and is pleased to find that the windpipe of a drake differs from that of a duck. But then, again, there was a good deal of "distribution," and he was bored by recollections of dreary geographical lessons,[1] and was not interested at learning that such or such a bird was found in some country with a long name not easy to pronounce.

With all these merits and defects, Yarrell's work, in all its editions, undoubtedly held the field, and there grew up more than one imitation of it—specious, pretentious, and misleading. One of these plagiarisms has been "embellished" (that, at least, is the word used by the publisher) with coloured figures; but unfortunately, among people who knew no better, as well as among people who ought to have known better, they have met with a success hardly inferior to the work from which they have been ingeniously and shamelessly "cribbed." This shows the exceeding popularity of the subject; but it is disgusting to find in nearly every school-library one or more of these piratical works—generally instead of the good, though more costly, original, though sometimes on the same shelf with it, as if the two were of equal authority. The common excuse is the high price of the "Yarrell," but no excuse can justify the corruption of youthful minds by ignorance, twaddle, and inaccuracy. Better hunger than poison—if both be deadly, one will kill more quickly than the other; and, since while there is life there is hope, the chance of proper aliment being timeously supplied exists in the former case, but in the latter even the antidote, if such a thing there be, may be exhibited in vain.

The work now begun by Mr. Saunders ought to abolish for ever the excuse just spoken of. This "Manual of British Birds" is cheap, marvellously cheap, and as fully illustrated[2] as ordinary boys can wish. That the design he has followed is certain to have a good effect few in a position to give an opinion can doubt, and his treatment of it is satisfactory, considering the enormous difficulties in the way. When one thinks of the vast amount that has been written about British birds by men who have written from their own knowledge—leaving wholly aside the pilferers above complained of—it will be evident that no ordinary discrimination is needed to extract the essence and serve it up on an octavo page and a half, or perhaps a few lines more, for this is practically the amount of letterpress at Mr. Saunders's disposal, the top of the first page being reserved for a woodcut of the species. But Mr. Saunders has been a "Zoological Recorder," and therefore has learnt the art of "boiling down." Occasionally there is a tendency to "straggle"—a favourite word of his, and one that is seldom apposite—and if verbal criticism be allowable, a protest might be made against "segregate" (more than once used) where *separate* is meant. But generally Mr. Saunders sets an admirable example in the matter of language, and one that all ornithological writers might well follow, since some of the more profuse of them have lately banished grammar and etymology to the outer planets, while style is a quality unthought of.

[1] All the same, the school-boy of forty or fifty years ago did learn *some* geography—a kind of learning that has lately been almost wholly dropped.

[2] The illustrations consist mostly of reproductions of the well-known "Yarrell" woodcuts.

There is one drawback in a work of this kind, and to some extent it is perhaps unavoidable. Mr. Saunders, following literally the scheme originally laid before him, and disregarding the exceptions therein provided for, devotes two pages to each species of bird. Now it is evident that this Procrustean plan cuts off many details of the greatest interest from what might be said of some species, and compels the story of comparatively uninteresting species to be stretched out. Among these last must of course be reckoned those which have only a few times made their way to the British Islands, and have scarcely a claim to be called "British" birds. In a work like this, Mr. Saunders, with the justly-earned reputation he possesses, might well have taken a new departure; but, unfortunately, four out of the twenty species included in his first part come under this condemnation. Their room, where every line is precious, would have been better than their company, and their introduction gives the beginner a wholly mistaken notion of the British fauna. Figures of the same absolute dimensions are often useful for certain purposes of comparison; but to treat the Rock-Thrush and three exotic species of Wheatears on an equality with our real denizens, that have inhabited these islands longer probably than any human beings, is to present a piece of distorted perspective. The practice was excusable in old days, and those that had to tread the ancient tracks were compelled to follow it; but here was an opportunity of striking out a fresh line. Of course there is great difficulty in drawing that line, for it must be drawn arbitrarily, but an arbitary line would be better than none. On a wharf a post-and-rail fence, or a suspended chain, may be placed almost at random, and people may say that it should have been a few inches nearer to, or further from, the brink, but if it saves them from falling into the water, few persons will not recognize the service it does.

It is a pity that almost the first word in this excellent book is one to which exception must be taken. Mr. Saunders has brought back the vulgar name of "Missel-Thrush," which some people fondly hoped had been for ever abrogated—as being either a corrupt abbreviation or wholly without meaning. Of course he can cite Willughby and a long string of subsequent authorities in his favour; but the "*auctorum plurimorum*" principle is directly opposed to sound scientific sense; and if Mr. Saunders will look up Willughby's predecessors—Charleton and Merrett—he will find that they do not admit the solecism. In a work of this kind, which cannot fail to have a great effect upon the rising generation of ornithologists, the least tendency to return to exploded errors is to be deplored. So much for criticism of the part which is now before me: I gladly say of the whole book—*Floreat*. ALFRED NEWTON.

THEORY AND USE OF A PHYSICAL BALANCE.

Theory and Use of a Physical Balance. By James Walker, M.A., Demonstrator at the Clarendon Laboratory. (Oxford: Clarendon Press, 1887.)

THE author states that this publication was originally intended as a chapter of a book on practical physics for the use of students at the Clarendon Laboratory, but that he proposes to publish each chapter when ready, without waiting for the completion of the work. This method certainly has some advantages both from the author's and the student's points of view. The practical study of physics, like that of all other sciences, and perhaps even to a greater extent than any other, is rapidly becoming specialized, with the necessary consequences that while each subdivision is expanding and becoming weighted with more details and technicalities, many diligent workers on one part of the subject are indifferent to the methods and appliances used in other branches. The numerous army of students in electricity and magnetism may take, for example, but a very superficial interest in the experimental side of acoustics or optics. At the same time it may be open to question whether it is advisable to break a work up into comparatively small fragments, as appears to be the intention in the present case. Like all other matter, the subject may lose in cohesion by being presented in too fine a state of division.

The instalment now issued gives a detailed and precise description of one of Oertling's balances used in the Clarendon Laboratory. The very clear explanation of the mechanism is assisted by three plates, one a photograph showing a general view, and the others line drawings of the various parts. Any want of clearness and definition in the photograph, which is not a particularly happy example of a collotype, is amply atoned for in the sectional diagrams.

Details are given of the methods adopted by the manufacturers to insure the accurate adjustment of the knife-edges, to test for their parallelism, for their being in the same plane, for the equality of the lengths of the arms, and of the masses of the pans, &c. The expression for the sensibility of the balance is determined from the general equations of equilibrium, and practical instructions are given with the necessary formulæ for performing some half-dozen of the usual physical operations with the balance, such as the determination of density of bodies heavier and lighter than water, of bodies in small pieces, &c.

In a thorough and somewhat elaborate investigation, which seems hardly suitable for a work intended as a handbook for a student entering on a course of laboratory instruction, the writer discusses the equations of motion of a balance, and shows that the method of determining the position of equilibrium from the amplitude of the oscillations on either side of the zero is not rigidly correct, since the beam with its adjuncts have not a simple definite period of vibration like a pendulum. The reassuring result is, however, arrived at, that the errors introduced are of a vanishing order, if the masses in the pans remain constant during a set of weighings.

Borda's method of counterpoising to eliminate errors of the instrument is recommended according to the usual practice, a mass heavier than the substance to be weighed being placed in the left-hand pan, while the substance and known masses are placed in the right-hand pan to bring the beam into an observed position of equilibrium. This procedure has advantages over the more tedious and less cleanly plan of exactly counterbalancing the substance with shot and fine sand, &c.

In allowing for the supporting force of the atmosphere, the author assumes that the average amount of moisture in the air may be taken as two thirds of the maximum possible. This seems a very high value for a closed and artificially heated room; certainly much in excess for air in a balance case which contains any substance, such as chloride of calcium, for absorbing the moisture. Perhaps it is the uncertainty as to the condition of the air thus artificially treated which causes the author to omit any reference to any of the hygroscopic substances usually employed.

The standard masses used at the Clarendon Laboratory are stated to be marked with their apparent value in air at 10° C. and 76 cm. of mercury. It is the usual custom, we believe, to mark the absolute value of the masses. For work not requiring the most refined precautions, the convenience of weights marked with their apparent value is obvious: no correction need be made for the supporting force of the air on the weights; but if that accuracy is considered sufficient, it seems an unnecessary refinement to complicate the formulæ by introducing a correction for the difference between the temperature of the air and of the water in which the substance is weighed.

The work is very clearly written and admirably printed, and will doubtless form, when completed (and we hope this will not be at a distant date), a valuable addition to the text-books on this subject. We have only noticed two mistakes in the text—the omission of the small over-weight w at line 23, p. 12, and of the length of the arm, a, at line 10, p. 16; but neither of these omissions affects the final results. The average student would, however, probably prefer that a larger portion of the space should be devoted to the more practical side of the subject, to hints and precautions to be taken in various operations; those given are very good, but they might with advantage have been extended. It would also, we think, be useful to indicate by numerical examples the order of magnitude of the various corrections to be applied, so that a student may judge what corrections may be safely omitted in the particular observation on which he is engaged. Some of the space given to the description of the instrument might, we think, have been more profitably devoted to a general account of other types of construction. Only a passing reference is made to the "short-beam" balance, and other modifications of the physical balance are not alluded to.

THE FLORA OF WEST YORKSHIRE.

The Flora of West Yorkshire, with a Sketch of the Climatology and Lithology in connection therewith. By Frederic Arnold Lees. 8vo, pp. 843, with a Map. (London: Lovell Reeve and Co., 1888.)

IT is just a quarter of a century since John Gilbert Baker's excellent book on the botany, geology, climate, and physical geography of North Yorkshire appeared,[1] and the present volume, devoted to West Yorkshire, is avowedly moulded on that model. Since then, English county and other local "floras" have become very numerous—many of them well executed, others indifferently. We do not mean to say that Mr. Baker was the originator of local "floras," for this branch of botanical literature early took root in this country, and has perhaps attained a development unknown elsewhere. Interesting among the earlier of such publications is John Ray's "Catalogus Plantarum circa Cantabrigiam nascentium," which dates (1660) nearly a hundred years before the first edition of Linnæus's "Species Plantarum." It is interesting alike for its botany and its botanical history. But the importance of exactitude in recording the localities of plants was not thoroughly realized by amateur botanists until they were stimulated thereto by the methodical and conscientious, though somewhat discursive, phytogeographical writings of the late Hewett Cottrell Watson. Now, thanks to the exertions of the competent few, English amateur botanists are so thoroughly educated in geographical botany at the beginning of their studies, that the careless, or, what is worse, the unprincipled, recorder of assumed localities of the rarer plants, is at once discovered and exposed. The latitudinal and altitudinal range of each species is now known with such accuracy that any new record outside of the known limits is at once scrutinized and tested, and only accepted on the best authority. It is a question, however, whether this sort of thing is not being overdone.

[1] We understand that a new edition is in preparation.

Mr. Lees expresses a hope that the acknowledged adoption of Baker's admirable method of inquiry and statement will not be regarded as too servile. We think it will not; and had the imitation been carried a little further, and the briefer and more condensed style of the pattern followed, it would have been a distinct advantage, because it would have reduced the size of the book without in the least impairing its value. The area of West Yorkshire is about 2750 square miles, and this is divided into ten drainage districts, varying in size from 30 square miles (Mersey tributaries) to 570 square miles—Don with Dearne; and the stations, or a selection of stations, in which a given plant is known to occur in each of these districts are given—in many instances, in what we should regard as excessive detail. Whether it would not have been better to amalgamate some of the districts, instead of adhering so closely to a principle as to maintain a very small portion of a drainage area as a distinct district, we will not pretend to decide; but there is no doubt it would have resulted in a considerable saving of space, which might have been profitably devoted to a brief exposition of the total geographical area of each genus and species.

With regard to the manner in which Mr. Lees has executed the task he undertook, there is ample evidence that he has spared no pains; and we have means of knowing that those most concerned are very grateful for such a store of well-sifted records. Nevertheless, this work, which forms the second volume of the botanical series of the Transactions of the Yorkshire Naturalists' Union, has its peculiarities, chiefly of a literary kind. On opening the book, we happened to light on the "Foreword," first of all, and we naturally expected that our author was a purist who wrote only Saxon English; but we soon discovered that uncommon words, irrespective of their origin, are dragged into use, and sometimes so piled up as to obscure not a little the meaning of the somewhat inflated sentences. However, this peculiarity is not carried so far as to constitute a serious defect in the work, and may be passed over with this allusion.

Very interesting are two introductory chapters on the climatology and lithology of West Yorkshire, specially in relation to plant-life, which many persons would doubtless gladly possess, apart from the enumeration of the plants of the region. In the list of pelophilous (clay-loving) plants, we note *Spiræa Filipendula*, a plant so strictly associated with chalk in the south of England, that we are surprised to find it among those characteristic of clay and mud-soils. Perhaps it was a slip of the pen for *S. Ulmaria?*

The total number of species of vascular plants enumerated is 1042, whereof 995 are phanerogams, which is equal to the whole phanerogamic flora of New Zealand, even after allowing 40 off for "critical species" of various genera. On the other hand, the vascular cryptogams of West Yorkshire are only 47 against 138 in New Zealand, of which 120 are ferns. Fortunately for the New Zealanders, and Australians too, for that matter, they are free from the "horse-tails," which are such terrible pests to farmers in some districts of this country; but seven species are indigenous in West Yorkshire.

Cellular cryptogams are also included in Lees's "Flora," and occupy about 250 pages. The enumerations of some of the groups are exceedingly imperfect —imperfect in consequence of their not having been investigated—and it would have been much more convenient for the majority of workers had this class been reserved for a separate volume. W. B. H.

OUR BOOK SHELF.

A Manual of Practical Assaying. By John Mitchell, F.C.S. Edited by William Crookes, F.R.S. Sixth Edition. (London: Longmans, Green, and Co., 1888.)

MITCHELL'S "Assaying" is so well known to all whom the subject concerns, that it is hardly necessary at present to do more than announce the appearance of a new edition. In this edition, as Mr. Crookes explains, much new matter has been introduced, and matter which had become obsolete has been omitted. Among the more important of the additions are descriptions of the "automatic sampling-machine," invented by Mr. D. W. Brunton; many new gas-furnaces and burners for the laboratory, devised by Mr. Fletcher, Messrs. J. J. Griffin, and others; new blow-pipe reagents and operations; new processes, dosimetric, volumetric, and calorimetric, for the partial and complete assay of iron ores, iron, steel, spiegeleisen, &c. In the copper assay the American system of fire assay is here, for the first time in this country, fully described. In the assay of silver, the action of bismuth on the ductility of this metal has received adequate attention. Much has been added about gold ores; and improved modes of assaying the precious metal and detecting it in poor ores are given. The number of woodcuts has been increased from 188 in the last edition to 201 in the present edition.

Asbestos, its Production and Use. By Robert H. Jones. (London: Crosby Lockwood and Son, 1888.)

THIS little book, written in epistolary style, though possessing little or no scientific value, contains an interesting account of the "asbestos" mines of Canada, and of the methods pursued in working the mineral in that country. It is precisely ten years since the first Canadian chrysotile mines were opened, and the annual yield at the present time appears to be more than 2000 tons, so that the new locality is rapidly becoming an important rival to the older and better-known asbestos mines of the Italian Alps. The author gives a brief description of the mode of occurrence of the mineral in the Serpentine belt which traverses the provinces of Megantic and Beauce in Quebec, and prophesies a wider development of this industry in the future; he does not, however, supply any such details as would suggest either the origin or the probable extent of the Canadian "asbestos," and the book contains no original observations of any scientific importance. The author does not appear to be aware of the difference between asbestos and chrysotile. The pages most interesting to general readers are those which contain an account of the latest uses to which the mineral is now applied; among which may be mentioned fire-balloons, theatre-curtains, fire-proof paint, filters, and letter-paper.

Industrial Instruction. By Robert Seidel. Translated by Margaret K. Smith. (Boston: D. C. Heath and Co., 1888.)

IN the years 1882 and 1884 industrial instruction formed the subject of much discussion in the Synod of the Canton of Zürich. Herr Seidel, who had long devoted earnest attention to the question, carefully answered all the objections to industrial education which were raised in the course of these debates; and the substance of his replies is embodied in the work translated in the present volume. If there is still anyone who has doubts as to the value of manual training in schools, he would profit largely by reading this little book. Herr Seidel's main point is that such training is absolutely essential in the interests of true education, and in working out this view he displays great intellectual resource and a thorough appreciation of the laws of mental growth. He is not afraid that when the need for this "new departure" is generally recognized the task imposed upon teachers will be beyond their capacities. "The training of teachers for industrial instruction," he says, "offers no difficulty, and will not (as has been asserted) by any means involve the necessity for two kinds of teachers. The teacher can very well master the new task, and if his prejudice has disappeared, will very gladly undertake it. Probably the imparting of industrial instruction will become a favourite employment of the teacher, because the change refreshes and the labour gladdens him."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Electric Fishes in the River Uruguay.

IN Sir Horace Rumbold's "Great Silver River" (London, 1887), the author, when on the Upper Uruguay above Uruguayana, speaks of a "kind of Electric Eel (*Gymnotus*) called here *Rayo* or Lightning, of the effects of contact with which, very curious and unrelateable stories are told."

The range of the *Gymnoti* is usually supposed to be confined to the waters of the Orinoco and Amazons and their affluents, so that it would be very desirable to ascertain what this supposed electric fish of the Rio Uruguay really is. Perhaps some of your readers in the Argentine Republic may be able to assist us in solving this problem, which would be best done by the transmission of specimens of the fish in question to the British Museum. P. L. SCLATER.

3 Hanover Square, London, W., June 8.

The Salt Industry in the United States.

MR. WARD in his letter to NATURE (May 10, p. 29), respecting the salt industry in the United States, makes no mention of the important and numerous contributions to the literature of that subject by Dr. Charles A. Goessmann, at the present time Director of the Massachusetts Agricultural Experiment Station, but formerly, from 1861 to 1869, chemist to the Onondaga Salt Company, at Syracuse, N.Y. While filling that position he investigated very thoroughly the salt deposits of New York, Michigan, Goderich, Canada, and Petit Anse Island, Louisiana, and his published reports and memoirs (some twenty in number) upon the salines, brines, and mineral springs of the country form, for the period which they cover, a very complete and valuable record of the salt industry in the United States.

Amherst, Mass., May 26. F. TUCKERMAN.

Prof. Greenhill on "Kinematics and Dynamics."

MAY I ask space for a few short comments on Prof. Greenhill's letter in your issue of May 17 (p. 54), so far as it is directed against myself.

(1) The "circumlocutions" referred to are not of my devising, but are current phrases which involve no ambiguity and are useful for avoiding frequent repetition.

(2) It is not true that "although such words as 'a force equal to the weight of the mass of 10 pound weights' do not occur in Prof. MacGregor's book, they are strictly derived from his definitions." According to my definitions, it is the body itself which has weight, not its mass; and the above phrase is therefore meaningless.

(3) Prof. Greenhill has not cited a single instance to justify his charge that I am at variance with my own definition of the weight of a body in the majority of the subsequent examples.

(4) He now seems to admit that in my hydrostatical equations pressure may be expressed in pounds on the square foot, but to claim that it can be done only in a clumsy manner. There is doubtless a certain clumsiness, but it seems to me to be due to the employment of a clumsy set of units.

(5) Your reviewer still demands that I should give the dimensions of the earth, not in terms of the actual metre, but in terms of what the original designers of the metre intended it to be; but he gives no reason for this strange demand.

(6) If the knot is a unit of velocity, the term *knots per hour* is of course redundant. I have always considered it an abbreviation, but have no means at hand of settling the point.

(7) Prof. Greenhill tacitly admits that he was in error in accusing me of misusing the term *elongation*.

(8) He makes no attempt to substantiate his statement that my equations of energy were not expressed in proper form.

(9) He does not answer my question as to which of the most recent treatises on dynamics my treatment of units shows me to have read without profit and discrimination.

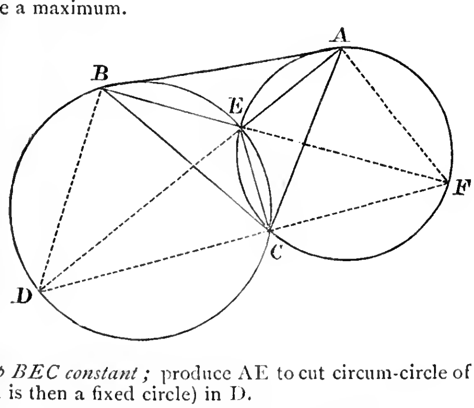
Edinburgh, May 31. J. G. MACGREGOR.

Further Use of Ptolemy's Theorem (Euclid, VI. D.) for a Problem in Maxima and Minima.

To find E within ΔABC such that

$$AE \sin BEC + BE \sin CEA + CE \sin AEB$$

shall be a maximum.



Keep BEC constant; produce AE to cut circum-circle of BEC (which is then a fixed circle) in D.

Then $\sin BEA = \sin BED = \sin BCD,$

$\sin AEC = \sin CED = \sin CBD,$

and $\sin BEC = \sin BDC;$

$$\therefore \frac{BC}{\sin BEC} = \frac{CD}{\sin AEC} = \frac{DB}{\sin AEB};$$

$$\therefore AE \sin BEC + BE \sin CEA + CE \sin AEB$$

is proportional to

$$AE \cdot BC + BE \cdot CD + CE \cdot BD,$$

and therefore to

$$AE \cdot BC + ED \cdot BC. \quad \text{(Eu. VI. D),}$$

which

$$= AD \cdot BC.$$

For a maximum AE passes through centre of circum-circle of BEC.

Similarly BE passes through centre of circum-circle of CEA. Let it cut it again in F.

$\angle BCE = \angle BDE,$

$= \angle BFA$ in same segment of circle through F, A, B, D,

$= \angle ACE.$

Similarly

AE, BE bisect $\angle$ CAB, ABC.

$\therefore$ E is the in-centre of ΔABC.

Bedford. E. M. LANGLEY.

Davis's "Biology."

IF I may argue from the contents of Mr. Davis's book, he should be a good judge of what constitutes "falling into a common mistake," and yet I cannot accept his opinion as to my having accomplished this feat. I have refrained from enumerating the common mistakes which his little book contains, but I am not prepared to allow him to lay down the law as to educational methods. In my opinion it is a grievous error to present any subject of study to University students under two aspects, that of "pass" and that of "honours." Whatever is worth doing at all (in academic exercises) is worth doing well, and no regulations sanctioned by any University Senate—however philanthropic, incompetent, and imperial—can make the perennial iteration of the statements in a cram-book concerning six plants and six animals a satisfactory substitute for the study of zoological and botanical science, or anything but a pernicious torturing of the youthful mind. THE REVIEWER.

M. FAYE'S THEORY OF STORMS.[1]

ACCORDING to M. Faye, "There exist in meteorology two theories diametrically opposed—one which considers air-whirls round a vertical axis, including cyclones, typhoons, tornadoes, and waterspouts, to originate in the upper currents of the atmosphere; and the other which considers each of these as the effect of a local rarefaction, giving rise at the surface of the ground, in an atmosphere in a more or less unstable condition, to an ascending current of air, which borrows a gyratory tendency from the rotation of the ground itself." Such is the opening sentence of the pamphlet before us, which embodies a *résumé* of M. Faye's discussions in the French Academy with those who do not accept his peculiar views on the generation of atmospheric disturbances.

M. Faye upholds the former theory with that incisive vigour which characterizes our Gallic neighbours, and attacks the meteorologists with whose writings he is acquainted, beginning with poor Franklin and ending with Sprung in 1885, without mercy, but at the same time without the smallest reference to physics apart from mechanics.

Before pointing out some of the grave errors of fact, as well as theory, into which we deem M. Faye to have fallen, it may be as well to see if we cannot attempt a reconciliation between these two opposite views, which are considered to be prevalent.

To avoid mixing up tornadoes and cyclones, which we hold to be, if not generically, at all events specifically, distinct, let us first consider the former alone. The point

[1] "Sur les Tempêtes." Par M. H. Faye. (Paris: Gauthier-Villars, 1887.)

that M. Faye insists upon all through is, that these arise solely through inequalities in the upper currents, causing gyration round a vertical axis, which, like a river eddy, is propagated from above downwards, by a *descending motion of the air*. M. Colladon, referring to M. Faye's view, describes the supposed action as "un mouvement tourbillonnaire aérien constituant à son intérieur une trombe *aspiratrice* à mouvement *descendant*." M. Faye, therefore, postulates two points: (1) that the movement commences above; (2) that it is propagated downwards by a descending motion, accompanied by gyration round a vertical axis. The opposite theory, as presented by M. Faye, is the exact inverse of this, since it makes the action (1) commence at the earth's surface; (2) propagate itself upwards; and (3) borrow its gyration from that of the earth. Here, however, we find ourselves distinctly at issue with M. Faye, for we do not believe that the leaders of modern meteorology entertain any such view as the latter. The surface of the earth is the most unlikely birthplace for a tornado, whirlwind, or waterspout. In order to maintain an ascending current, the air must be nearly saturated, and this will generally occur only in and near the lowest cloud stratum. The vertical temperature gradient and disturbances which start the action, will likewise operate most effectively at this level, so that all the conditions which unite to cause a tornado will tend to commence at some distance above the earth's surface. On the question of level, therefore, we may invite M. Faye to agree with us. Then comes the question of the downward propagation.

The entire gist of the question appears to us to lie in this downward propagation. The physical theory developed by Ferrel and Sprung makes the action commence in a slight upward motion in unstable air, due to a temperature inequality or some other cause, the only other condition being a gentle gyratory motion relative to some central point, which is never wanting in a cyclonic area. Once the motion is started, and the air which feeds it is nearly or quite saturated, the action will go on and be propagated downwards, not by a descent of the *air*, but by the transference of the physical conditions which favour the continuance and maximum development of the "courant ascendant." The increasing rapidity of gyration of the air as it approaches the axis, however gentle it may be at starting, only allows it to partially feed the initial and continually reproduced vacuum, which is thus compelled to draw its supplies chiefly from the non-gyrating air at the lower end of the aërial shaft. As this is drawn upwards, the centrally aspired surrounding air is made to gyrate more rapidly (partly by the friction of the superjacent rotating layer), and thus the gyratory and other *conditions* are propagated downwards until a balance is struck between supply and demand.

The theory thus sketched may be termed the modern theory of aspiration as applied to tornadoes, and will, we venture to think, be found to meet all M. Faye's objections to the first crude notions which prevailed in past years from a study of a few isolated surface conditions.

Before proceeding to notice the objections which M. Faye brings against the existence of either an upward current or any sort of aspiration in tornadoes, we must first touch upon the cognate question of cyclone generation, which he explains on the same principles;[1] and here, without attempting to give any review of the modern theory, which involves as a primary condition a horizontal temperature anomaly over a considerable area, we may observe that the two main objections brought by M. Faye against the ordinary view of their formation are, (1) that it assumes the existence of centripetal currents, and hence aspiration towards their axes; (2) that it gives no explanation of their movements over the earth's surface.

[1] There is no real connecting link between the two, *i.e.* the smaller cyclones do not begin where the larger tornadoes leave off. The average size of 600 tornadoes in the United States was found to be 1085 *yards*. The average size of the cyclones is as many *miles*.

With respect to the first objection, M. Faye draws attention to a principle which he develops on p. 46, according to which the isobars in the temperate zone do not correctly represent the motions of the air in a cyclone, and says we must look at the isobars in a tropical cyclone if we wish to arrive at correct conclusions.

Here, according to M. Faye (pp. 2 and 46), where "by the *ancient* theory the direction of the wind ought to cut the isobar at an angle of nearly 90°, the angle is sensibly nothing; the pretended centripetal component disappears; and the isobars and the wind arrows display an almost rigorous *circularity*." Again, on p. 12 he ridicules the idea of a barometric gradient in the *tropics*, "where the wind blows precisely *along* the isobars." It is with no desire to indulge in mere polemic that we take up the gauntlet thus thrown down, but the magnificent work of that most careful and renowned inductive meteorologist Prof. Loomis which he has been lately revising, enables us to show most conclusively not only that in the latitude of the Philippines which is nearly the equatorial limit of true cyclones, the direction of the wind in a particularly violent and well observed typhoon cut the isobars right through at the large angle of 62°; but that an extensive comparison of similar conditions, embraced in a large number of violent storms in different latitudes, shows that the angle between the winds and the isobars *increases as it should do according to theory from the poles to the equator*.

The accompanying figure represents the observations accurately, except that the isobars were not as there exactly circular; while the following table shows at a glance how entirely opposed M. Faye's statement is to the true facts, in the very region where he says, "les isobares elles-mêmes dessinent sur le sol comme les flèches du vent un édifice cyclonique *non encore déformé*." We have no hesitation therefore in saying that these observations of Prof. Loomis not only give the death-blow, if one were needed, to the purely circular theory of Reid and Piddington, but constitute a *conclusive* argument against M. Faye's theory of downward gyratory currents and non-aspiration in *cyclones*.

Inclination of the Wind to the Isobars in VIOLENT *Storms.*

	Latitude.	Inclination of wind to isobar.
	° ′	° ′
Arctic Regions ...	70 56 ...	28 35
Atlantic Ocean ...	56 15 ...	30 6
United States ...	45 0 ...	40 3
India and Bay of Bengal...	20 48 ...	57 12
Philippine Islands ...	14 35 ...	62 12

It is true both from theory and observation that the inclination is less on sea than on land, and usually less as we approach the centre; but the above cases suffice to show the danger which might attend an unmodified adherence to the circular theory, or the rough empirical law of Buys Ballot, which is its practical expression. Dr. Meldrum, F.R.S., of Mauritius, as we have pointed out in a previous article (NATURE, vol. xxvi. p. 31), has frequently exposed the danger of following the purely circular theory, and in a number of the Journal of the Mauritius Meteorological Society for July 1883, he mentions a case in which the captain of the ship *Calédonien* on January 24, 1883, deliberately ran it into the centre of a cyclone by following the circular rules. Fortunately he subsequently became aware of his error, and altered his course just in time to escape the centre.

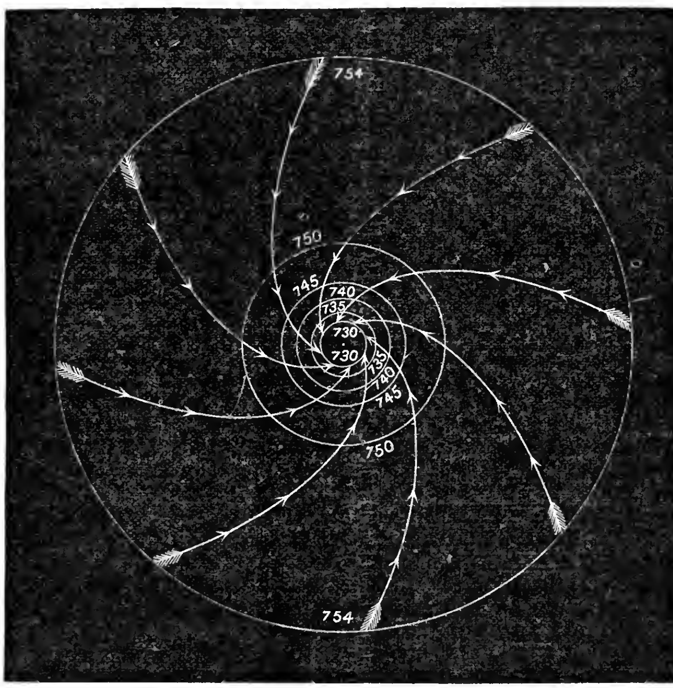
The second objection brought by M. Faye against the physical theory of cyclones is, that it cannot explain their general motions and course over the earth. We admit that the partial theory, sketched in his opening statement, which he considers to represent the modern meteorological views, could scarcely hope to account for this; but if he will allow the meteorologists to rise with him a few thousand feet above the ground, he will find that the "*drift* theory," of which he appears to regard himself as the discoverer and sole exponent, has for some years been recognized as one of the chief possible causes of the motion of cyclonic systems.

Prof. Ferrel, a representative *deductive* meteorologist, considers the motions of the upper and middle currents to be the *principal* cause of the motion of a cyclone in longitude; its motion in latitude, which is generally towards the poles, being due to the inherent tendency which a mass of fluid gyrating in the same sense as the hemisphere in which it is situated, has to press towards its pole.

Prof. Loomis, an equally representative *inductive* meteorologist, is more cautious; but in his latest work,[1] while admitting the existence of numerous other physical factors to account for the frequently anomalous movements of storm centres—which M. Faye elegantly ignores—he agrees in attributing their *general* directions of translation to the *general* extrinsic movement of the atmosphere at the time, at some height above the surface, in combination with the intrinsic mechanical principle just mentioned.

That these are not the *sole* causes of the motion of cyclones may, however, be freely admitted, and we quite agree with the remark which M. Faye triumphantly quotes in italics from Dr. Sprung's recent "Lehrbuch," on p. 14, viz. that "none of the theories which have been put forward will alone suffice to *completely* explain the motion of translation of cyclones."

Many facts, such as the observed direction of the upper clouds over and surrounding a cyclone, the velocities at the surface in different quadrants, the retardation of the barometric minima at mountain stations, and the frequently small elevation reached by the entire disturbance (not more than 6500 feet according to Loomis)—which are all entirely overlooked by M. Faye—tally more with



The Manilla cyclone of October 20, 1882. The arrows denote the direction of the wind; the circles denote the isobars at intervals of 5mm.; the inclination of the arrows to the isobars was constant all through, and = 62°·2.

a species of wave-motion by which the conditions are continually reproduced in a certain direction than with the drift theory, and in any case require other and additional causes for their complete elucidation.

We therefore entirely dissent from M. Faye's dictum that the failure up to date to discover all the causes of the motion of cyclonic areas is to be considered "an irremediable check to their meteorological theory," and we equally fail to recognize how the drift theory as put forward by him strengthens his case in favour of downward motion in tornadoes, or advances our knowledge of cyclone and tornado motion one step beyond the position it has already reached.

To return to tornadoes.

Fully armed with his preconceived theory of gyration, due to inequalities in the velocity of the upper currents, causing a downward motion of air along the axis of the whirl, and completely disregarding all evidence of upward motion or aspiration, M. Faye devotes the main part of his pamphlet to criticizing in turn the various experiments and opinions of MM. Weyher, Colladon, Lasne, and Schwedoff, with the result that he likes none of them, for the very obvious reason that, while they differ from one another in certain points, they all demand aspiration and upward motion along the axis.

We have not space to follow all these attacks in detail, but we venture to think that before attempting to strangle all adverse hypotheses it would have been wise if M. Faye had placed his own theory on a substantial basis of either physical and mechanical principles, or experiment. As it is, the sole foundations he appears to rest upon are (1) the analogy of the river eddy, and (2) the *fancied* absence of all indications of upward aspiration either during or after the passage of a tornado.

Regarding (1) we need only refer to M. Weyher's experiments, which we recently reviewed in NATURE, in

[1] "Contributions to Meteorology," chap. ii p. 142, revised edition, 1887.

order to point out that, by causing rotation at the surface, M. Weyher found himself unable to produce a gyratory system extending downwards into the liquid from the area of rotation. On the other hand, he always found rotation, whether above or below, produce aspiration (accompanied by gyration) *towards* the area initially set in motion. According to these results, therefore, river eddies produced by inequalities in the horizontal flow cannot propagate themselves *below the area of flow disturbance.*

Now it is precisely this very form of river eddy which M. Faye takes as his analogue to the aërial tornado, and it is here that his argument fails; for, while he draws attention to the system of downward motion and gyration in an eddy caused by an outflow through an orifice in the bottom of a vessel containing liquid, where such motion and gyration is evidently caused by the outflow, he is obliged to avoid all reference to outflow at the surface as a cause in the supposed downward atmospheric gyrations. At the same time he imagines that an entirely similar system takes place, in the river, and the atmospheric eddies, as in that produced by efflux, which propagates itself downwards simply through initial rotations taking place in the upper portions, of the liquid in the one case, and of the atmosphere in the other. We have no hesitation in saying that even if such an action were possible, which we strongly doubt, it is in direct opposition to all that we know of tornadoes, either deductively from physical theory, or inductively from the facts which have been recorded up to date.

It would be a laborious, though at the same time distinctly easy, task, to point out the numerous physical facts which accord with the upward aspiration and downward propagation of *conditions* only, and which are utterly opposed to M. Faye's theory of downward motion of the *air*. It would be equally easy to quote numerous observations showing the objective reality, which M. Faye questions, of upward motion in a tornado. Prof. Loomis, for example, who is noted for his caution, relates the following pregnant incident in his own life, in his preface to the revised "Contributions":—"In February 1842 a tornado of unusual violence passed within 20 miles of Hudson. As soon as I received the news, I started out with chain and compass to make a thorough survey of the track, and succeeded to my entire satisfaction. As the tornado passed over a forest of heavy timber, I had the best opportunity to learn the direction of the wind from the prostrate trees; and, by measuring the direction of the trees as they lay piled one upon another, I determined the successive changes in the direction of the wind. *The facts demonstrated incontestably that the movement of the wind was spirally inward and upward, circulating from right to left about the centre of the tornado.* This tornado was but an incident in a great storm which swept over the United States ..."; and he goes on to say that the results of his subsequent investigation of the latter showed that neither the purely circular theory of Redfield nor the purely inward theory of Espy was correct. The truth, as usual, lay between these two extremes, and the wind, like that shown in the diagram of the Manilla cyclone, really blew in a spiral, curving in towards the centre. Any of the accounts published by the United States Signal Service afford equally strong evidence in favour of both aspiration towards the centres and motion up the axes of the tornadoes. Thus, in the Report furnished by Rev. Charles Brooke, of the West Cambridge tornado of August 22, 1851, the following remark occurs: "No one saw any object driven *downward* by it, but all testify to its taking things *up*" (the italics are in the original); and then follows a list of articles taken *up* and carried, such as boards and slates, to a distance of 3 miles, a large barn 15 feet, a freight-car 60 feet, &c.

Again, in the Official Report of the Iowa and Illinois tornado of May 22, 1873, different witnesses say: "Saw boards whirling round in the funnel." "While the whirlwind was on the river, the water ceased to flow over the dam, although the river at the time was high." "Saw rails *flying out from the summit* [of the column]; an average rail weighs about forty pounds." And we may close the list with one quoted by Ferrel as a well-authenticated case, in the tornado at Mount Carmel, Illinois, June 4, 1877, in which "the spire, vane, and gilded ball of the Methodist church were carried 15 miles to the north-eastward." The whole evidence, in fact, both in tornadoes, and in their milder form of water and sand spouts, is overwhelmingly against M. Faye's views, and in favour of upward motion and aspiration to their very summits.

In his endeavour to bolster up a theory weak at all points, M. Faye seizes upon the well-known phenomenon of the central calm in cyclones, and cites one which occurred in the typhoon at Manilla on October 20, 1882, as proving the general existence of a downward current. In this case, while the thermometer during the first half of the storm marked 24° C., it rose during the passage of the central calm to 31° C., after which it fell again to 24° C. The relative humidity followed analogously inverse changes, falling from 98 to 53—an extraordinary degree of dryness for such a climate. With reference to this circumstance, M. Faye quotes with considerable triumph a remark of Dr. Sprung to the effect that "such a characteristic phenomenon can only be explained by admitting the existence of a descending current at the centre of this cyclone." Locally, and for a short space upwards, there might have been; but these particular features, accompanied by a clearing of the sky, and known as the "eye of the storm," are the exception and not the rule, even in tropical cyclones. It is, moreover, readily seen that if there were a descending current of any extent or velocity in cyclones it would necessitate *an outflow along the surface* for some distance round their centres—a condition utterly opposed to all observation and experience. M. Faye makes one more attempt to support the differential-current-motion hypothesis of tornado and cyclone generation, by referring to certain empirical laws of the relation of the former to the latter disturbances, deduced by Mr. Finley, of the United States Signal Service. For example, (1) the fact that tornadoes are usually found in the south-south-east or dangerous octant of a cyclone; and (2) a law formulated by M. Faye himself, according to which their trajectories, as traced by the areas of destruction, are parallel to those of the cyclones in which they are generated.

The first of these facts has been known for some time, and applies equally to thunderstorms. M. Faye considers it to arise from the air shot *down* from the upper currents reaching its maximum velocity "where the velocity of translation is added to that of rotation," an idea which concentrates in a truly tornadic manner two fundamental errors which pervade his work. Modern investigation has shown that the velocities of rotation and translation in cyclones are quite independent, and is in this matter as far ahead of M. Faye's view as his knowledge of cyclonic systems is superior to that of Franklin, who had no isobaric charts to help him.

Again, the south-east portion of a cyclone is precisely where, according to the corrected theory of aspiration, the conditions are most favourable to the production of local and parasitical disturbances of equilibrium, and since such disturbances take their birth in or just below the cloud-strata, their trajectories will naturally tend to follow the course of these higher strata, which in this part of the cyclone *generally* coincides with that of its translation. The violent motion, moreover, which M. Faye considers to be such an essential primary condition in the generation of tornadoes is by no means necessary, as Prof. James Thomson, among others, has pointed out in a recent paper before the British Association (British Association Reports, 1884, p. 641.)

Besides the objections we have all along pointed out to the existence of the downward current in cyclones, it renders M. Faye perfectly helpless when he contemplates an anticyclone. In the presence of such a formidable foe he is completely disarmed. Here, just where a downward current would come in really useful, he finds he has *used it all up*. All he can say, therefore, is that they have nothing cyclonic about them, which is quite true.

M. Faye concludes by drawing up a list of questions which relate to the phenomena exhibited by cyclones, tornadoes, and waterspouts, and which he considers yet unsolved. Some, doubtless, still await a more complete explanation, but we think the list might be considerably curtailed if M. Faye would descend, if possible, in one of his favourite eddies, and meet the *aspiring* meteorologist half-way. Atmospheric phenomena seldom present themselves in the form of purely mechanical problems. If, as M. Faye says, the question "is not one which can be treated by actual methods of rational mechanics on which everyone can agree," we are equally confident that it is one whose solution cannot be attempted without the aid of rational physics, or without reference to the facts already established by observation.

E. DOUGLAS ARCHIBALD.

THE VISITATION OF THE ROYAL OBSERVATORY.

THE Report of the Astronomer-Royal to the Board of Visitors of the Royal Observatory was read at the annual visitation on June 2.

One of the first points touched on in the Report is the threatened railway invasion of the Observatory.

The subject of approaching railways has again, after a lapse of many years, engaged our serious attention. Early in March notice was received from the Home Office of a proposal to carry a railway (in extension of the authorized Bexley Heath Railway) in a tunnel across Blackheath, the nearest point being 840 yards from the Observatory. As there was reason to believe that this railway might injuriously affect the Observatory, preliminary observations of the effect produced by trains on the existing Greenwich and Maze Hill Railway were at once commenced, the observations being made on six nights with the transit-circle, and the disturbance in the image of the wires, as seen by reflection from the trough of mercury, being noted. It resulted from these experiments that trains on this railway caused great disturbance during their passage, not only on the section between Greenwich and Maze Hill, the nearest point of which is 570 yards from the transit-circle, but also on the line beyond Greenwich on the London side and beyond Maze Hill on the Woolwich side. The distances of the Greenwich and Maze Hill stations from the Observatory are about 970 and 670 yards respectively. There was also evidence of disturbance caused presumably by trains on the Lewisham, Blackheath, and Charlton line, at a distance of about a mile from the Observatory, but we could only infer the times of passage of these trains from the published time-tables.

In order to establish conclusively the connection between definite disturbances and trains, arrangements were made to note the times of arrival and departure of trains on the Greenwich line and at Blackheath, facilities for doing this having been courteously given by Mr. Myles Fenton, the Manager of the South-Eastern Railway. Observations were made on this plan on five nights, one observer being stationed at the transit-circle to record all disturbances of the reflected image, while another observer travelling up and down the Greenwich line, and a third observer at Blackheath, noted the times of arrival at and departure from the stations. It was found that the disturbance was very great during the passage of trains between Greenwich and Maze Hill, the reflected image being invisible while the train was in the tunnel, at a minimum distance of 570 yards, and that there was considerable disturbance during the passage of trains through the Blackheath-Charlton tunnel, at a distance of a mile, the reflected image becoming occasionally invisible. As the tunnel of the proposed railway would be similar in character to this, but at half the distance, it was concluded that it would cause so great a disturbance as to make delicate observations impossible. On my notifying this to the Admiralty, the Bill was opposed on the part of the Government, and as a consequence of this the clauses authorizing the construction of the railway across Blackheath were abandoned.

I may here mention that the extension of the London, Chatham, and Dover Railway from Blackheath Hill to Greenwich, which was authorized in 1881, is now in course of construction. I hope that, though the terminus of this line is distant only 620 yards from the Observatory, the tremor from trains will not have sufficient time to produce the full accumulated effect in the short interval between Blackheath Hill station and the terminus. But if at any future time a further extension of this line should be proposed, the question would require very careful consideration in the interests of the Royal Observatory.

The following statement shows the number of observations made with the transit-circle in the period of 356 days ending May 10, 1888:—

Transits, the separate limbs being counted as separate observations	5304
Determinations of collimation error	294
Determinations of level error	351
Circle observations	5067
Determinations of nadir point (included in the number of circle observations)	331
Reflection-observations of stars (similarly included) ...	503

About 350 transits (included in the above number) have been observed with the reversion-prism, to determine personality depending on the direction of motion.

The very bad weather in the first four months of this year has seriously affected the number of observations with the transit-circle.

The total number of observations made with the altazimuth is as follows, the observations having been as usual restricted to the first and last quarters in each lunation, except during the winter, when, in the absence of suitable objects for equatorial observations, the moon was observed throughout the lunation.

Azimuths of the moon and stars	354
Azimuths of the azimuth mark	114
Azimuths of the collimating mark	116
Zenith distances of the moon and stars	209
Zenith distances of the collimating mark......	116

In consequence of the building operations for the extension of the computing-rooms the collimating mark was dismounted on November 9, and the view of the azimuth mark has been obstructed by the new building from the beginning of December. Since then the collimation and azimuth errors have been determined entirely by observations of high and low stars. It is proposed, when the work on the new building is completed, to select two azimuth marks, one distant and the other sufficiently near to be seen in the foggy weather of the winter months. For distinct vision of the latter a lens of very long focus would be required, and it would thus be available strictly as a collimating mark.

All will regret to hear that no progress has been made since the date of the last Report in the construction of the new 28-inch refractor, owing to difficulty in obtaining the crown disk. The flint disk made by Messrs. Chance seems to be satisfactory, but up to the present neither that firm nor M. Feil's successor has succeeded in making a crown disk.

Attempts have been made to show if anything is gained in sidereal photography by using curved plates. For this purpose a 4-inch photographic object-glass by Dallmeyer, belonging to one of the photoheliographs, was mounted at the end of June in a light wooden tube, and firmly attached to the side of the telescope tube and parallel to it, to carry out experiments on the extent of field available on plane and curved plates respectively, the latter being moulded by Messrs. Chance to a radius of 22 inches, corresponding to the curvature of the field, if the circle of least confusion be taken for the image. We read:—

Forty-one photographs have been taken of the Pleiades and other objects with different exposures and in different parts of the plate, 13 of these being on curved plates. In these experiments the Sheepshanks refractor was used as directing telescope, the image of a star being kept on its cross-wires during the exposure of a plate by means of the slow motions. The plates measure 6 inches × 6 inches, representing $5\frac{3}{4}^\circ \times 5\frac{3}{4}^\circ$, and it is found that on the flat plates the star images are sensibly circular to a distance of nearly 2° from the centre of the field, while micrometric measures of these plates show that for some distance beyond this limit the relative places of stars can still be measured with an accuracy exceeding that of meridian observations, and with no sensible systematic error depending on magnitude or duration of exposure. Comparison of the results on flat and curved plates respectively indicates that the advantages of using the latter are doubtful. As the Dallmeyer object-glass is peculiar in having the flint outside, it was reversed in the cell in the course of the experiments, and some photographs were taken with it in this position, the flint being inside. It appeared on comparing the results that a somewhat better field is obtained with the flint outside. A photographic object-glass of 6 inches aperture and 6 feet focal length, made by Sir H. Grubb for experiment, was mounted at the end of April in place of the 4-inch object-glass, and some trial photographs of stars have been taken with it.

Special arrangements were made for observing occultations during the total eclipse of the moon on January 28, observers being stationed at nine instruments, but clouds covered the moon almost continuously during totality. Various devices were adopted with a view to facilitating the observation in rapid succession of the faint stars occulted during the eclipse. In the case of two instruments the eye-piece was mounted excentrically at the distance of the radius of the moon's image from the axis, so that without disturbing the position of the telescope any point of the limb could be brought into the centre of the field. For setting the position-circles rapidly in the dark, cardboard circles with notches at important points or with the figures indicated with luminous paint, were found very useful.

The spectroscopic observations of motions of stars in the line of sight have been continued. The recent observations of Algol confirm the previous results indicating orbital motion, but further observations are required to establish the fact. At the request of Mr. Lockyer, the spectra of α Orionis, α Herculis, γ Cassiopeiæ, and β Lyræ have been examined on several occasions.

That the daily record of the solar surface is gradually getting more complete is clearly shown by what happened in the year 1887, in which Greenwich photographs are available on 188 days; photographs from India or Mauritius filled up the gaps in the series on 173 days, thus making a total of 361 days out of 365 on which photographs have been measured in this year.

The sun has been free from spots on 106 days in the year 1887, and the areas of both spots and faculæ have diminished since the date of the last Report. With the exception of a fine group seen during three rotations in May, June, and July, and of three other groups, one in July and two in December, all of these being in the southern hemisphere, there has been a complete absence of conspicuous spots. The entire spotted area has rarely amounted to 1/2000 of the sun's visible hemisphere, and the mean is less than one-sixth of that recorded in 1883, being intermediate between those for the years 1875 and 1876.

In view of the diminution of the current work as the minimum of sunspots approaches, the further discussion of the results of former years has been commenced, and arrangements have been made through the Solar Physics Committee to complete the Greenwich results as far as practicable by the measurement of photographs taken elsewhere, particularly at Ely and Cambridge, U.S. From the beginning of 1882 the photographic record is practically complete, the measurement of Indian photographs to fill up gaps in the Greenwich series having been undertaken from December 22, 1881. The further discussion of results has, therefore, been commenced from that date, and the projected areas of spots (uncorrected for foreshortening) have been formed to May 29, 1885, and from the beginning of 1886 to the end of 1887. The ledgers in which the areas and positions of the spots of a group are collected and the mean area and position of the group, deduced for each day and for the whole period of visibility, have been formed for 1886 and 1887, and their completion for the years 1882 to 1885 will now be taken in hand. Two new forms have been prepared to exhibit the distribution of spotted area on each day for every degree of latitude and for every 10° of longitude, mean results being taken for each rotation and for each year.

With regard to magnetic observations we read that the only important change is the substitution, since October last, of a wooden bar loaded with lead, of the same size and weight as the declination-magnet, for the brass bar hitherto used for determination of the torsion of the suspending skein, a very weak trace of magnetism having been detected in the brass bar.

The earth-current observations have been attended with some difficulties. We read:—

The earth-current wires, which were damaged by the snowstorm of 1886 December 26, were not completely repaired till August 1887, when it was found that the earth-plate at Angerstein Wharf had been stolen, another earth-plate being then supplied. A renewal of the earth-current wires concurrently with the telegraph wires on this portion of the South-Eastern Railway was arranged, in concert with Mr. Leonard, but this has not been carried out owing to a rise in the price of copper. Five measures of resistance of the earth-current wires have been made since the last Report, but the results are not satisfactory, owing presumably to the bad condition of the wires. On the line from Angerstein Wharf to Ladywell, $7\frac{1}{2}$ miles in length, the measures of resistance range from 220 to 285 ohms, and on the Blackheath to North Kent East Junction line, 5 miles long, the measures range from 230 to 262 ohms. Under these circumstances it seems hopeless to attempt to express the measures of ordinates on the earth-current sheets in terms of the electrical units until the conditions of the circuits have been improved. A further difficulty arises in discussing the small diurnal inequality on the earth-current registers in consequence of the circumstance (to which attention was first drawn by Mr. A. J. S. Adams, of the Post Office Telegraphs) that there is a slight dislocation in the Angerstein Wharf to Ladywell trace shortly after sunset with sudden return to the original position shortly before sunrise, representing an increased current from Ladywell to Angerstein Wharf, or a diminished potential at Angerstein Wharf during the night hours. Possibly this may be connected with the electric lighting in the vicinity of the earth plate. It appears to have commenced in 1883, becoming more pronounced in 1884.

The following are the principal results for the magnetic elements for 1887:—

Approximate mean declination . .	17° 47′ W.
Mean horizontal force . .	3·9419 (in British units) 1·8175 (in Metric units)
Mean dip	67° 25′ 45″ (by 9-inch needles) 67 26 20 (by 6-inch needles) 67 27 13 (by 3-inch needles)

In the year 1887 there were only three days of great magnetic disturbance, but there were also about twenty other days of lesser disturbance for which tracings of the photographic curves will be published, as well as tracings of the registers on four typical quiet days.

The mean daily motion of the air in 1887 was 275 miles, being 9 miles below the average of the preceding twenty years. The greatest daily motion was 829 miles on March 23; and the least, 59 miles on November 16. The only recorded pressure exceeding 20 pounds on the square foot was 20·5 pounds on April 6.

During the year 1887, Osler's anemometer showed an excess of about 17 revolutions of the vane in the positive direction N., E., S., W., N., excluding the turnings which are evidently accidental.

The number of hours of bright sunshine recorded during 1887 by Campbell's sunshine instrument (Prof. Stokes's improved pattern) was 1401, which is about 190 hours above the average of the preceding ten years. The aggregate number of hours during which the sun was above the horizon was 4454, so that the mean proportion of sunshine for the year was 0·315, constant sunshine being represented by 1.

The rainfall in 1887 was 19·9 inches, being 4·8 inches below the average of the preceding forty-six years.

There has been no failure in the automatic drop of the Greenwich time-ball, but on four days the ball was not raised on account of the violence of the wind.

The automatic drop of the Deal time-ball failed on six days owing to interruption of the telegraphic connections, and on two days high wind prevented the raising of the ball. There has been no case of failure of the 1 p.m. signal to the Post Office Telegraphs.

There have been twenty-three failures in the automatic signals from the Westminster clock since the date of the last report. The error of the clock was insensible on 25 per cent. of the days of observation, 1s. on 38 per cent., 2s. on 20 per cent., 3s. on 15 per cent., and 4s. on 2 per cent.

Provision has been made in the estimates for the expense of a re-determination of the difference of longitude between Greenwich and Paris, and correspondence has been carried on with the French authorities on the subject. The regretted death of General Perrier occurred before any definite plan had been settled; but his successor, M. le Commandant Bassot, has taken the matter up warmly in concert with Admiral Mouchez, and the French Bureau des Longitudes has approved the scheme, which is to include a determination of the longitude of Dunkirk. Three French delegates (M. Lœwy, M. Bassot, and M. Defforges) propose to visit Greenwich very shortly to settle the details of the plan of operations which it is intended to carry out in the autumn. In preparation for the work, Mr. Turner and Mr. Lewis have observed for practice, by eye and ear, a number of galvanometer signals sent by another observer and automatically registered on a chronograph, five sets of ten signals having been recorded on each of seven days.

The Report concludes as follows:—

In my last Report it was suggested that the instrumental equipment of the Observatory should be supplemented by a photographic refractor of 13 inches aperture (equatorially mounted) to enable Greenwich, as the National Observatory, to take its share in the scheme for forming a photographic map of the heavens, and for thus extending our knowledge of the places of the fixed stars. Consequent on the resolution of the Board of Visitors at the last visitation, I brought this question of the insufficiency of our instruments for the present wants of astronomy to the notice of the Admiralty and of the Chancellor of the Exchequer, and the matter is still under the consideration of the Government. If the Royal Observatory is to take part in this work of carrying out one of the principal objects for which the Astronomer-Royal was appointed, it appears to be essential that a decision should be arrived at without delay, in view of the circumstance that thirteen Observatories (including those of Melbourne and Sydney in our own colonies) have already ordered their instruments, which are to be completed by the end of the present year.

Allusion was made in the last Report to the increased demands made on the Observatory in recent years both by the scientific and the general public, and in view of the consequent development of work it now becomes necessary to review the position of the establishment, which was constituted many years ago, when the conditions were very different. In order to understand the difficulty of the present situation it is necessary to bear in mind the following facts:—In 1835 there were five assistants (excluding the chief assistant), having no computers to superintend, no extraneous work beyond the care of a relatively small number of chronometers for the Navy, no magnetic and meteorological observations, no altazimuth observations, no spectroscopic and photographic observations. At the present time there are eight assistants (excluding the chief assistant) having fifteen computers to superintend, and of this staff two assistants are absorbed by the magnetic and meteorological branch, one by the altazimuth, and two by the spectroscopic and photographic branch, leaving only three assistants to do the astronomical work, which in 1835 required five assistants, and in addition to perform all the extraneous duties which the Astronomer-Royal has felt it desirable to undertake in the public interest.

Under these circumstances it becomes a matter for serious consideration whether, unless adequate provision be made for the primary objects of the Observatory, extraneous work, such as the supply of time-signals, may not have to be dropped. The service of hourly time-signals throws considerable work on myself and the staff of the Observatory, and, as it is purely voluntary, it appears to me that a condition of its maintenance must be that arrangements shall be made to enable the proper work of the Observatory to be carried on and suitably developed.

INDUSTRIAL TRAINING.

At a meeting held at the Mansion House on Friday last, in support of the scheme for establishing Polytechnic Institutes in South London, an able and interesting speech was delivered by Lord Salisbury. Having pointed out that of late years much had been done for primary education, he went on to show that a sound system of secondary education for the great mass of the people was not less necessary. Secondary education, as we know it at present, had been established for the benefit of classes who in the main had not to work for their living. Plainly, therefore, it was not adapted to the needs of the working classes. "What we have now to do," he continued, "is to provide an education which will develop for each man the faculties that Nature has given him in such a manner that he may be as active, profitable, and prosperous a member of the community as possible." Lord Salisbury then passed in review the efforts which have been made in London to meet the demand for technical instruction, and concluded as follows:—

"I have only one more word to say, just to call your attention to another aspect of this case and to commend it to your efforts. We live in a time when men multiply fast, but apparently the means of supporting them do not multiply as rapidly; when there is vehement competition and occasionally intervals of deep depression. And if you should look more closely, you will find that one cause at least of this phenomenon is that man, as the mere owner of muscle, is being edged out by another and more powerful competitor. Merely as an agent of physical force, as the possessor of the power of labour, the steam-engine is a competitor which drives him easily out of the market. And more and more the mere unskilled labour is being made unnecessary by the development of the forces which mechanical science has discovered. And as the world goes on, you must expect this tendency to increase. You must expect mechanical force to become more varied and more powerful and more cheap, and the competition with human arms and limbs to become more hopeless. But there is one region where the machine can never follow the human being, and that is in the exercise of thought. In skill, in cultivated mind, in the power to adapt the processes of thought to the laws of Nature, in all that we call 'skilled labour' of the highest kind, in that man must always have a monopoly, and need fear no encroachment from the competition of the steam-engine. It is to the development of his powers in that respect that the increase in the means of subsistence and the opening of new paths of self-support must be found. On all of us, in whatever position we are, is pressing, as one of the most anxious subjects of public care, the discovery of methods by which the teeming millions of this country shall be able to maintain themselves in a prosperous, decent, and comfortable condition. We cannot find in their unskilled labour a satisfaction of that want. The difficulties are enhanced by the fact that our neighbours in other countries have been sensible of the superiority which skilled education can confer, and have not been slow to take advantage of it. If we will not be left behind in the race, if we desire to find any satisfactory solution for the deepest and the most inscrutable problem of our time, if we wish our complex community and high civilization to be maintained secure from all the dangers which the presence of unfed, unprosperous, untaught millions must bring upon them, we shall do our utmost to give a healthy and a rapid development to the secondary education of the working classes."

The *Times*, commenting on the meeting addressed by Lord Salisbury, says:—

"The Prime Minister spoke of the occasion as marking an era in the development of secondary education. The expression is scarcely too emphatic. Many of those present at the Mansion House have been for years labouring for that cause, and often with little confidence that they would ever see the produce of the seed which they sowed. Now, however, the husbandman's hopes rise, for he discerns everywhere lusty shoots flourishing, and he knows that a harvest is at hand. It is no small matter to find Government recognition of the importance of manual or technical education in a Bill which will enable any School Board to promote it. What London has done other cities will do, and here much has been done, and still more is imminent. The Polytechnic and the Beaumont Institutes are admirable pioneers. The projected Institutes for South London will soon, we should hope, be established; and the Charity Commissioners have promised to grant £50,000 in aid of an Institute for the south-west parishes north of the river on condition that the same amount is contributed by the district. What limits are there to the possible benefits from a network of such institutions over London and other great cities? Even if they fail to sharpen the wits of our workers, and to prepare them for their part in that struggle which the Prime Minister eloquently described as the course of civilization, if the foreign clerk continues to oust our own youth, we may count with certainty on deep and far-extending good from institutions mingling instruction with recreation, uniting many of the good points of clubs and schools, serving to some as ladders for ambition to climb with, to others as refuges from the public-house, and introducing intellectual light into the dark places of our cities. For many a man and woman, especially at the outset of life, narrow means would lose all terror if there were open of an evening an Institute such as was described yesterday; and it would be the best palliative of that dull monotony which in some walks of life is more injurious, as it is immensely more common, than downright viciousness."

For many a day, as our readers know, we have been urging the necessity for the establishment of a proper system of technical instruction. The subject is one of such pressing importance that we have returned to it again and again, seeking to present it in many different aspects; and Lord Salisbury's speech and the article in the *Times* may be taken as indications that large classes of the community have at last begun to understand that the nation has no time to lose in setting about a task which ought long ago to have been most seriously undertaken. Even if the question had little direct relation with economic interests, it would be for many reasons desirable to secure for manual training a place among our educational methods. Attention has hitherto been too exclusively devoted in schools to such knowledge as may be derived from books. It is necessary, from the strictly educational point of view, that teachers should aim at a wider, more direct, and more practical development of the mental powers of their scholars. But other and even more fundamental interests are also concerned. The leading nations of the world, our rivals in industry and trade, have already perceived the benefits to be secured from a thorough mastery, on the part both of employers and employed, of the principles of science as applied to agricultural and manufacturing processes. The result is that in many of the best markets, where our supremacy as a trading people was formerly unquestioned, we find ourselves at a disadvantage; and it is certain that unless we place ourselves on a level with our competitors we shall have to pass through some very bitter national experiences. The question is really one of life and death for England. It is a question whether in the near future there are or are not to be sufficient employment and remuneration for the vast and growing masses of her population.

WEISMANN ON HEREDITY.[1]

THE fundamental property of all living matter is assimilation and consequent growth; and reproduction is merely discontinuous growth. This is most apparent in the Protozoa, where the primitive form of reproduction—division into two parts—is common. Each part exactly resembles the other part, and both the parent. Heredity in them merely means identity of bodily substance, and consequent identity of vital phenomena. In Metazoa there is a sharp distinction between reproductive cells and body cells. In many cases it is certain that the reproductive cells of each new organism arise directly from the reproductive cells of the parent. Here there is as manifestly a continuity or identity of the germ-plasma as in the Protozoa. As has already been explained by Prof. Moseley in this paper, Weismann extends this phylogenetic continuity of germ-cell, or at least of germ-plasma—the essential constituent of the germ-cell—to all the Metazoa.

In the Metazoa, the germ-cells, instead of remaining single, give rise to the vast number of somatic cells which compose the adult structure. The form, arrangement, and succession of these depend on the germ-plasma; and as there is continuity of this from generation to generation it follows that the structures derived from it are identical in each generation. Obviously this view excludes the possibility of the inheritance of acquired characters. But this inheritance has been proved neither by observation nor by experiment, and it has been impossible to conceive any satisfactory mechanism by which it could be accomplished.

Weismann believes that the theory of the inheritance of acquired characters is not required to explain the phenomena of the organic world. In the production of an acquired character two forces are at play, and these forces in relation to the organism may well be called *centripetal* and *centrifugal*. The centrifugal forces are ultimately referable to the molecular constitution of the germ-plasma, and are transmitted with the other properties of the germ-plasma from generation to generation. Changes in the centrifugal forces due to that mixing of plasmata which is the object of amphigonic reproduction constantly occur. Adaptation and differentiation result from the action of the environment (centripetal forces) on these continual changes in the possibilities of the organism. Not acquired characters, but the internal possibilities of them, are transmitted: not the results, but the centrifugal causes of them, are transmitted and accumulated by natural selection. An example will make this clear. Giraffes are certainly descended from short-necked forms. According to the old theory, during life their ancestors, by constantly stretching to reach higher and higher branches of the acacias, &c., on which they fed, elongated their necks a

[1] "Ueber die Vererbung," von Dr. August Weismann. (Jena, 1884.)

little. Each addition to the neck so acquired was transmitted to the descendant, and by accumulation of the changes thus produced the modern long-necked condition was attained. According to Weismann, what happens is this. In each generation slight variations in the length of the neck, as in the other parts of the body, occur. These variations are due to constitutional causes which are transmitted. When greater length of neck became important to the animal, those animals with necks a little longer or capable of being stretched out a little further, would have the advantage, would survive longer, and leave more offspring. The offspring, inheriting the constitution of their parents, would inherit this tendency to have longer necks. By the continual elimination in many generations of the short-necked forms, and by the seizing hold of each naturally-occurring variation, the long-necked condition would finally appear.

As variations are constantly occurring, natural selection must constantly be at work to maintain the standard of any organ. Whenever an organ ceases to be of use, or even when it becomes merely of subordinate utility, this selective maintenance falls into abeyance. A state that Weismann calls *Panmixia* results. Variations below the standard cease to be eliminated, and the organ slowly degenerates. In this way is explained degeneration through disuse: degeneration from conditions that are not harmful but merely unnecessary. In many cases organs that are not used degenerate very much during individual lives, but this occurs through failure of nutrition. Weismann believes such effects not to be transmitted. Were these effects inherited, useless organs must inevitably disappear very much more rapidly and completely than there is evidence for.

Instincts are elaborated, not by the accumulation of transmitted individual experience, but by continual selection of mental variations in the required direction. For instance, the instinct to avoid enemies arose not by accumulation of experience, for experience of the inconvenience of being devoured could hardly be transmitted, but by the naturally more timid forms surviving, and leaving more offspring than their less wary brethren.

Talent and even genius often run through several generations; and certainly mental powers can be much increased in individual lives. But the exhibition of talent and genius depends on a combination of many physical and mental conditions in which constitutional variation is ever present, and these variations are undoubtedly inheritable. Moreover, the history of families of conspicuous ability (as, for instance, that of the musical family Bach) shows that the highest development often occurs in the middle of the series, while the theory of the transmission of acquired characters would demand to find it at the end.

Selection of variations best explains cases of adaptation to new climates. But the immense influence of climate conditions on nutrition in each ontogeny must be taken into account.

Qualitative changes at first present some difficulty, but it must be remembered that qualitative changes are nearly always at bottom quantitative. A surface appears naked, though covered with many small hairs; or light-coloured, though scattered pigment-cells are present. Quantitative variations in such conditions certainly occur, and are certainly transmitted, and natural selection can readily change the number or size of hairs or pigment-cells, and produce so-called qualitative results.

It is not claimed as yet that the inheritance of acquired characters can be excluded in every case. But increasing knowledge of the conditions of life and of the functions of organs causes ever a larger and larger part of the phenomena of the organic world to be explained by the selection of naturally-arising variations.

P. CHALMERS MITCHELL.

IMPERIAL GEOLOGICAL UNION.

REFERRING to my letter on the above subject, published in NATURE, vol. xxxvi. p. 146, I beg to communicate, for the information of those interested in the matter, the substance of a report made to the Royal Society of Canada at its meeting on May 22, in Ottawa.

The Committee reported that it had, as directed, printed the letter of Sir William Dawson to the President of the Royal Society, and the first report of the Committee, and had circulated these extensively, sending them especially to geologists and Societies in Great Britain and the colonies and dependencies of the Empire. A large number of replies had been received, testifying to a somewhat general wish for union and co-operation.

The matter was then laid before the Council of the Royal Society, with the view of holding a Conference in London under its auspices. The subject was taken up by the Council in October last, and a resolution was passed and communicated to the Committee to the effect that, having regard to the existing condition of the question of scientific federation, and the various contingencies that may occur during the next few years, they do not see their way to summon such a Conference as that recommended.

In view of this resolution it was felt to be useless for the present to attempt any farther action. Still, as the desire for and appreciation of the benefits of the union contemplated seemed to be very general, and as opportunities may occur later for giving it a practical form, it was thought best by the Royal Society of Canada to continue its Committee, with power to correspond with other bodies and with persons interested. The undersigned will therefore be glad to receive any communications on the subject.

Some misconception appears to exist as to the relations of the intended movement to the International Geological Congress which is to meet in London in September next. They have in reality no connection, except that, under certain contingencies, they might be mutually helpful.

A Union of British Geologists might exercise an influence for good in connection with the plans for unification of classification, nomenclature, and mapping, which have occupied the attention of the Congress; but its function would rather be the positive one of uniting workers throughout the wide area occupied by the British Empire, and enabling them more effectually to co-operate in the extension of actual knowledge, in giving mutual aid, in enlarging the mental vision of local and special workers, in making accessible to isolated labourers the common stock of knowledge, and in preventing the interference and discordance which result from disunited effort.

That there are difficulties in the way of the realization of such a plan as applied to British and colonial geologists in the first instance, and ultimately to all English-speaking geologists, there can be no doubt; but they are continually diminishing, in consequence of greater facilities for intercourse and the rapid growth of scientific work in the various outlying parts of the Empire. The idea is thus a fruitful one, certain to be realized in the future; and possible even at present if a central nucleus could be secured for an Imperial organization. It is not impossible that the large gathering of English-speaking geologists in London in September may afford opportunity for further discussion of the plan; and if the invitation which it is understood will be given by our friends of the United States to hold the next meeting in America be accepted, this may constitute another step in the same direction.

Montreal, May 31.

J. WM. DAWSON.

NOTES.

THE Laboratory of the Marine Biological Association at Plymouth is now approaching completion, and, after the opening ceremony on the 30th inst., it will be, in all essential respects, ready for work. The salt-water reservoirs have, after several delays, been filled, and the water is now circulating freely in the tanks of the aquarium. The fittings of the main laboratory are complete on the north side, and will give accommodation for seven naturalists, besides the Resident Director. In addition to this there are the physiological and chemical laboratories, all the fittings of which are now in place, and the library is in process of formation. The Association stands very much in need of presents of books, and it is hoped that those who are interested in its work, and have duplicate copies of biological works on their shelves, will be disposed to present them to so deserving an institution. At the opening ceremony on the 30th, upwards of a hundred members and their friends are expected to be present. The fact that Parliament is in session will keep away many of those who take a liberal interest in the Association, but it is hoped that Sir Lyon Playfair, Sir Edward Clarke, and Sir Edward Birkbeck will be present to represent the Parliamentary interest. Prof. W. H. Flower will be the presiding zoologist, and with him will be many well-known men of science, including Profs. Ray Lankester, Milnes Marshall, McIntosh, C. Stewart, Dr. Günther, Mr. Adam Sedgwick, and many others. The Hydrographer has stated his intention to be present, and the naval and military element will be fully represented by the commanding officers of both services at Plymouth. The Fishmongers' Company, which has been so munificent a patron of the Association, will be fully represented by its Prime Warden, Sir James Clarke Lawrence, and several members of the Court. They have kindly undertaken the hospitable duties of the occasion, and there can be no doubt that the *déjeûner* at the Grand Hotel, and the speeches that may be expected to be made there, will form a most important part of the day's proceedings.

THE annual meeting for the election of Fellows of the Royal Society was held at the Society's rooms in Burlington House on June 7, when the following gentlemen were elected: Thomas Andrews, F.R.S.E., James Thomson Bottomley, M.A., Charles Vernon Boys, Arthur Herbert Church, M.A., Prof. Alfred George Greenhill, M.A., Lieut.-General Sir William F. D. Jervois, R.E., Prof. Charles Lapworth, LL.D., Prof. T. Jeffery Parker, Prof. John Henry Poynting, M.A., Prof. William Ramsay, Ph.D., Thomas Pridgin Teale, F.R.C.S., William Topley, F.G.S., Henry Trimen, M.B., Prof. Henry Marshall Ward, M.A., William Henry White, M.I.C.E.

DR. S. H. VINES, F.R.S., Fellow of Caius College, Cambridge, has been elected to the Sherardian Professorship of Botany at Oxford.

THE King of Sweden, who was elected an Honorary Member of the Linnean Society at the centenary anniversary meeting of that Society held at Burlington House on May 24 last, gave an audience on Friday afternoon to the President (Mr. W. Carruthers, F.R.S.), Secretaries (Messrs. B. D. Jackson and W. P. Sladen), and Librarian (Mr. Harting), and inscribed his name in the album wherein the names of all Fellows and Honorary Members have been inscribed since 1788. The Royal signatures include those of George IV., William IV., Queen Victoria, Prince Albert, the Prince of Wales, the King of the Belgians, the King of Saxony, and now the King of Sweden.

THIS week the University of Bologna is celebrating the eighth century of its existence. A congratulatory Greek ode has been written by Prof. R. C. Jebb, who represents the University of Cambridge as its senior delegate at Bologna. The verses, which are composed in the metres of Pindar's eighth Olympian ode, are suggested by the circumstance that the University of Glasgow, in which Prof. Jebb holds the Chair of Greek Literature, is the only University in this country of which the model was taken directly and exclusively from Bologna.

THE second annual *soirée* of the Middlesex Natural History and Science Society was held at the Society's rooms, 11 Chandos Street, Cavendish Square, on Thursday evening last. Lord Strafford, the Lord-Lieutenant of the county, President of the Society, was in the chair. Many objects of scientific interest were exhibited.

THE Hon. J. Collier has undertaken to paint the portrait of Prof. Williamson, which is to be presented to University College.

THE Conferences convened by the London Chamber of Commerce to consider the question of commercial education led to the appointment of a Committee for the full discussion of the subject. This Committee nominated a sub-Committee, among the members of which were Sir John Lubbock, Sir Henry Roscoe, and Sir B. Samuelson. A scheme for the improvement of commercial education has now been drawn up by the sub-Committee and sent to various business men, schoolmasters, and other authorities on education, with a request for practical suggestions. The scheme, as it stands, proposes as obligatory subjects for examination for a commercial certificate: (1) English; (2) Latin; (3*a*) French; (3*b*) German, Spanish, or Italian; (4) history of British Isles and colonies, general and modern history, including commercial history; (5) geography, physical, political, commercial, and industrial; (6) mathematics; (7) drawing. Proficiency is also required in at least one of the following: physics, chemistry, natural history, commerce, and political economy.

PROF. LÜTKEN, Director of the Zoological Museum of Copenhagen, has addressed a strong appeal to country people in Denmark to protect the sand grouse. He points out that the only countries in which the birds nested in 1863 were Denmark and Holland, but that owing to people gathering and eating the eggs no birds were hatched. He trusts that this wanton conduct may not now be repeated. The Professor feels sure that the bird can be acclimatized in Denmark, as the sandy cliffs and shores of that country are particularly suited to its breeding. The Zoological Gardens in Copenhagen have obtained a live specimen of the bird, caught in the Island of Fünen. Flocks upwards of a hundred in number have of late been seen in many parts of Denmark.

ONE of the largest pine-trees ever grown in Sweden was felled the other day in Lapland. It measured over 120 feet in height, and was 12·5 feet in diameter 2 feet from the ground.

ON the evening of May 14, about 10 p.m., a brilliant meteor was seen at Kalmar, in Sweden. It was about the size of an ordinary plate, the colour being pale yellow, and it had a train about 100 feet in length. It went in a north-westerly direction, apparently only some little height above the ground, and exploded some distance from the town with a noise like that of burning gunpowder. During its progress a whizzing sound was distinctly heard.

IN vol. iv. Part 4, of the *Indian Meteorological Memoirs*, Mr. J. Elliot gives a list and brief account of the south-west monsoon storms generated in the Bay of Bengal during the years 1882–86. This list, which contains Nos. 47–101 of the series of storms, is a continuation of that given in the sixth paper of the second volume of the *Memoirs*, and is accompanied by yearly and monthly track charts. Some of the principal storms have been fully discussed in previous parts of the *Memoirs* and in the Journal of the Bengal Asiatic Society. The retreat of the south-west monsoon in October 1866 was followed by the occurrence of three cyclones at intervals of about a fortnight. They presented such marked peculiarities that they have been specially investigated. All were generated in the immediate neighbourhood of the Andamans. The first, which began to form on November 2, is an example of a class of storms, of occasional occurrence, which pass across Southern India into the Arabian Sea, and it lasted for a fortnight. It is the first example of its kind which has been fully worked out. The second, which was also a very violent storm, was formed on November 13, and affords a marked illustration of the effect of a mass of land in modifying the motion of a cyclonic disturbance. The third storm formed on December 7, and was in many respects exactly similar to the first, excepting that it was comparatively feeble at sea and short-lived on land.

AT the meeting of the French Meteorological Society on May 1, M. Poincaré presented calculations and synoptic charts showing mean barometric heights at latitude 30° and 10° N., for every day from December 9, 1882, to December 15, 1883, and on the parallels of 40°, 50°, and 20°, for a number of selected days, and pointed out certain relations which he considered existed between the barometric movements at these latitudes, and the positions of the sun and moon, and the effect of these on the displacements of the region of the trade winds. M. Renou made a communication upon the unsatisfactory condition of actinometry, and showed that the values obtained varied according to the instruments used, the force of the wind, &c., and he submitted some of the observations made during seven years at the Observatory of the Parc Saint-Maur. The Secretary presented, on the part of M. Pictre, of Pau, a plan for the graphical representation of local observations, in connection with general weather charts, with the view of facilitating local predictions. M. d'Abbadie urged the desirability of developing the study of earthquakes, and offered to give particulars as to an inexpensive form of seismograph, and as to the observations required, to persons willing to undertake such investigations.

THE Committee of the Association for the Oral Instruction of the Deaf and Dumb have issued their Report for 1887. They express much regret that in a great many instances the children are too early removed from the school established by the Association. Parents and guardians appear to think that as soon as a fair amount of speech and lip-reading has been acquired there is no longer any need for special training. Notwithstanding this drawback, the Committee feel assured that in each year the friends of oral instruction increase in numbers, and that the time is not far distant when the manual alphabet and sign language, if retained at all, will exist only as a special requirement for cases of imperfect vision and semi-imbecility. At the Training College two grades of certificates are now granted—first-class for head, second-class for assistant teachers. During the year 1887 eleven female teachers attended the Training College, of whom six obtained first-class, and two second-class certificates.

A NEW edition of Sir Walter Buller's "History of the Birds of New Zealand" has been issued. Without going over identically the same ground, the author gives in this edition a more thoroughly complete account of the birds of a country which is second in interest to none in the world as regards its natural history. A melancholy interest attaches to the avifauna of New Zealand, where so many of the indigenous birds, remains of a most ancient fauna, are either extinct or on the verge of extinction. Sir Walter Buller deserves well of every naturalist for the wonderful pains and energy he has shown in getting together the facts for the life-histories of many of these birds, which in a few years no one will be able to procure, and he has accomplished his task ably. The scientific portion of the work and the full descriptions of the species are as well written as the accounts of the habits. The plates have been done by Keulemans, and produced by chromolithography, but, like all illustrations of birds produced by this process, they are not quite satisfactory. Insects appear to us to be capable of illustration by chromolithography, but birds do not lend themselves so readily to this method. The delay in production is excessive, and the cost very considerable, while the efforts to produce a striking plate result in some loss of exactness in the colouring of the bird, this being not strictly accurate in many cases. That this should result when the best lithographic draughtsman of birds in the world has been employed, and unlimited money been spent on the production of the plates, clearly shows us that chromolithography is, and ever will be, inferior to hand-colouring.

THE fifth monthly part of the "Cyclopædia of Education" (Swan Sonnenschein) has now been issued. The complete work will include about twelve parts.

A SECOND edition of Mr. S. R. Bottone's "Electrical Instrument-making for Amateurs" (Whittaker and Co.) has just been issued. In compliance with the request of several correspondents, the author has added a short article on the telephone.

SIR DAVID SALOMON'S useful "Management of Accumulators and Private Electric Light Installations" (Whittaker and Co.) has already reached a fourth edition. The author has thoroughly revised the work and made some additions, including the "Rules and Regulations for the Prevention of Fire Risks," as laid down by the Committee of the Society of Telegraph-Engineers and Electricians.

MESSRS. GUY AND CO., at Cork, and Messrs. Simpkin, Marshall, and Co., London, have published a "Guide" to what the enthusiastic author calls "the most picturesque tour in Western Europe." By this he means a tour in the south-west of Ireland. The little volume is illustrated.

MR. LELAND'S work on "Practical Education" has reached a second edition. He will now follow up the ideas set down in this book by a series of illustrated hand-books on the minor arts and industries. The series will begin with a manual on "Drawing and Designing."

"A FRESH-WATER YARN," an illustrated account of a boat-voyage up the River Avon, is announced for immediate publication by Mr. Elliot Stock.

MR. T. FISHER UNWIN is about to publish a second edition of Mr. Edward Newman's "Birdsnesting and Bird-skinning." The work has been revised, and practically re-written, with, in addition, directions for the collection and preservation of birds, and a new chapter on bird-skinning, by Miller Christy.

MESSRS. E. AND F. N. SPON have in preparation "The Drainage of Fens and Low Lands by Gravitation and Steam Power," by W. H. Wheeler; "Practical Notes on Pipe Founding," by James W. Macfarlane; and "A System for the Construction of Crystal Models on the Type of an Ordinary Plait," by John Gorham.

THE administrators of the schools of the Caucasus have just brought out the first volume of the works of the late General Uslar. No explorer of the Caucasus has done so much as Uslar did for the ethnography of the region, yet his works are little known. In 1862 he published his remarkable researches into the Abkhazian language, and laid the foundations for a rational, most appropriate, and easy transcription of this and other Caucasian languages. Later on, he brought out similar works on the languages of the Tcherkesses, Avarians, Lakhes, and so on. He did not merely compile more or less perfect vocabularies of each language, but thoroughly learned each in turn, with the help of natives, and he considered his work worthy of publication only when he could bring out an elaborate grammar. Unhappily all his works were merely lithographed in a limited number of copies. Now the first volume has appeared at Tiflis under the title of "Ethnography of the Caucasus." It contains Uslar's work on the Abkhazian language, and several smaller articles on the principles of transcription of the Caucasian languages; on the languages of the Tcherkesses and Ubykhes; and on the grammar of the Svanetian language.

THE sporadic geographical distribution of the *Aldrovandia vesiculosa*—an aquatic plant of the family of Droseraceæ—long ago attracted the attention of botanists. Grisebach and De Candolle discussed it, and Caspary made it the subject of two well-known monographs, trying to explain the strange distribution of the *Aldrovandia*, a few individuals of which had been discovered, after much hunting for them, in localities so far apart as Arles, Bordeaux, and a very few other places in France; at isolated spots in Italy, Tyrol, and Hungary; in Silesia; about Pinsk in Lithuania; and at Calcutta. Since Caspary wrote, it has been discovered also in Brandenburg, South Bavaria, and at two other spots in Prussia. Schweinfurth discovered it in Central Africa, and Ferd. Müller in Australia; and Russian explorers have found it on the Lower Amu-daria, and in the delta of the Volga. Taking up again the whole question as to the causes of its sporadic extension, in the *Trudy* of the Kazan Society of Naturalists (vol. xvii. fasc. 1), M. Korzchinsky shows that in the delta of the Volga it grows especially in thickets of rushes. There, in the most inaccessible parts of the thickets, the water is covered with flowers of the *Aldrovandia*, while in open places it is very scarce, and the few individuals discovered rarely flower. MM. Herbich and Berdan noticed the same circumstance on the Tiniecki Lake about Cracow; and M. Korzchinsky concludes that the *Aldrovandia vesiculosa* is a feeble plant which cannot compete with other aquatic plants, and is thus compelled to seek for refuge in the shaded spots amidst the rushes where no other aquatic plants grow. The spots where the *Aldrovandia* grows now must be regarded as a few remnants of a wide region over which it formerly extended, and M. Korzchinsky compares it in this respect with the *Trapa natans*, which is also disappearing.

How far north did the Caspian Sea extend during the post-Pliocene period? This question has often been considered by geologists and geographers. Marine deposits, undoubtedly Caspian—that is, containing a fauna which is now characteristic of the Caspian Sea—have been recently found as far north as the Samara bending of the Volga; so there can be no doubt that during the post-Pliocene period a gulf of the great Aral-Caspian basin penetrated north, up the present valley of the Volga, as far as the 54th degree of north latitude. A few years ago Prof. Golovkinsky raised the question whether the post-Pliocene sediments which fill up the great depression on the middle Volga at its junction with the Kama, were not also deposited in a great lake which stood in connection with the Caspian; and this question is now answered by M. Netchayeff, who has investigated these deposits. He communicates to the Kazan Society of Naturalists (*Trudy*, vol. xvii. fasc. 5), that the brown-yellow sandy clays on the Kama about Tchistopol (55° 20′ N. lat.), contain the following fossils: *Dreyssena polymorpha*, most characteristic of the Aral-Caspian deposits all over the Trans-Caspian region, *Pisidium fontinale*, *Paludina achatina*, *P. impura*, *Limnæus fuscus*, *Helix pulchella*, and the *Hydrobia caspia* (Eichwald). The latter, according to Grimm, is one of the forms now in the Caspian Sea which are found only in that sea. We must therefore conclude that the Kazan depression of the Volga, now about 150 feet above the sea-level, *i.e.* 235 feet above the level of the Caspian, was a part of that sea at a period so close to our own as the post-Pliocene.

THE cod and whale fisheries in the north of Norway have entirely failed this spring, and it is suggested that the non-appearance of the former is due to the low temperature of the sea this season. Thus the Russian naval officers stationed on the Murman coast found in May only a surface temperature of from 1° to 2° C., and along the Norwegian coast it has been lower still. As to the whale-fishing, only 40 animals had been captured by the end of April against 200 last year. It is maintained that the present wholesale slaughter carried out by Norwegian and Russian steamers equipped with harpoon guns will eventually extirpate these animals, and some measure for their preservation is contemplated. Advices from the Arctic regions state that there was an enormous mass of drift-ice in those waters during this spring. Two sealers, the *Hekla* and the famous *Vega*, were imprisoned for more than a month in the ice to the north-east of Norway.

IN the very useful scientific methods whereby movements record themselves in curves, photography and a point moving on a smoked surface are perhaps those forms which yield the most delicate curves. In the French Société d'Encouragement, M. Mascart has called attention to a useful modification by M. Fénon, in which a bent tube of tempered steel forms a siphon, dipping at one end in a reservoir of ink, and at the other being shaped like a pen point, which is brought near the moving paper (the sloped section outwards). Capillary force prevents outflow when the apparatus is at rest. A fine trace is produced by this pen, without interruption by the most rapid displacements, and without sticking when at rest. M. Wolf, of the Paris Observatory, has used the system for getting records of air-pressure, temperature, wind, &c., with the best results. The reservoir needs charging only once a week; and using inks mixed with glycerine a single charge has been found to suffice for a barometer record of more than six months.

IN a recent interesting lecture, opening his course at the Collège de France, M. Ribot gave a sketch of contemporary psychology. The science in France might be characterized by one expression—"the era of monographs." There was no comprehensive work like that of Wundt in Germany; such were certainly very useful, but, like vast cathedrals, they always needed repair at some point. In psychology proper, the part belonging to logical operations, to reasoning, as principle of the unity of perceptions, had been well studied; and perhaps the most important results had been reached in the study of the nature and physical conditions of the image. The psychology of movements, especially those expressing thought, had yielded a rich harvest; while the great amount of experimentation in hypnotism, and the foundation in 1885 of a Society of Physiological Psychology (impossible twenty years ago), showed the vitality of French studies. In England, the principal contributions were in comparative psychology, represented chiefly by the work of Lubbock and Romanes. Germany was the centre of psycho-physics. Wundt's laboratory at Leipzig, founded in 1879, had acquired great renown, and, last year, had twenty students of different nationalities working in it. M. Ribot justified those studies, which had been rather depreciated in France. The predominating tendency in Italy was criminal psychology (better known as criminal anthropology)—the three chiefs of the school being Lombroso, mainly a biologist; Ferri, a sociologist and statistician; and Garofals, a jurist. It had gained several adherents in France, and there were symptoms of its invading Spain. In the United States, as in Germany, public instruction had almost alone played the part of initiation in the psychological movement; in England, the work had been chiefly done by books (Mill, Bain, Spencer, &c.). Four American Universities now gave special teaching in physiological psychology, and had laboratories, psycho-physics being the dominant study. A journal devoted to experimental psychology was started at the Johns Hopkins University, last November, by Prof. Stanley Hall. The work of James at Harvard was also referred to. Allusion was further made to Russia, which might be expected to take a good place in the psychology of the future.

THE additions to the Zoological Society's Gardens during the past week include five Pea-fowls (*Pavo cristatus*, 2 ♂, 3 ♀) from India, presented by Her Majesty the Queen; a Pagoda Owl (*Syrnium sinense*), a Horsfield's Scops Owl (*Scops lempiji*) from Penang, presented by Mr. C. B. Ricketts; three Grey-breasted Parrakeets (*Bolborhynchus monachus*) from Monte Video, presented by Mrs. Macnab; a —— Gull (*Larus* ——) from Massowah, presented by Mr. D. Wilson-Barker; a Chilian Skunk (*Conepatus mapurito*) from Chili, a Black-necked Swan (*Cygnus nigricollis*) from Australia, a White-throated Monitor (*Varanus albogularis*) from South Africa, purchased; a West Australian Great Kangaroo (*Macropus ocydromus* ♂) from West Australia, two Wandering Tree Pies (*Dendrocitta vagabunda*) from India, received in exchange; a Japaneese Deer (*Cervus sika* ♀), a Burrhel Wild Sheep (*Ovis burrhel* ♀), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *JUNE* 17–23.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 17

Sun rises, 3h. 44m.; souths, 12h. 0m. 43·7s.; sets, 20h. 17m.: right asc. on meridian, 5h. 45·4m.; decl. 23° 25′ N. Sidereal Time at Sunset, 14h. 3m.

Moon (at First Quarter June 17, 7h.) rises, 12h. 1m.; souths, 18h. 33m.; sets, 0h. 52m.*: right asc. on meridian, 12h. 19·2m.; decl. 2° 56′ N.

GEOGRAPHICAL NOTES.

THE paper read at Monday's meeting of the Royal Geographical Society was on Hudson's Bay and Hudson's Strait as a navigable channel, by Commander Markham. It was really a brief sketch of a much larger memoir on Hudson's Bay which Commander Markham has prepared, and which will ultimately be published by the Society. For some years investigations have been carried on with a view to discover whether the navigation of Hudson's Bay could be so depended on as to justify its acceptance as a regular trade route, in conjunction with a railway, to the more northerly parts of Canada. Commander Markham briefly sketches the history of navigation in Hudson's Bay, and concludes with the results of his own visit in the summer of 1886 on board the *Alert*. The result, he states, of all the experience gathered from voyages during two centuries, and from observations at the stations, is that Hudson's Strait is perfectly navigable and free from ice in August and later in the season. It must be remembered that this passage has been successfully accomplished nearly every year for the last two centuries, while the vessels that have been employed on the service have been ordinary sailing-ships, dependent entirely on wind and weather. It is very rare indeed that they have failed to get through, and still more rare that any of them have been destroyed by the ice. It appears from the official records of the Hudson's Bay Company that Moose Factory, on the southern shore of the bay, has been visited annually by a ship since 1735, with but one exception, namely in 1779, when the vessel for once failed to achieve the passage of the strait. The percentage of losses by shipwreck among these vessels employed in Hudson's Bay is far less than would have to be recorded in a like number of ships engaged in general ocean traffic. Commander Markham pointed out that until quite recently only sailing-vessels attempted to navigate Hudson's Bay, and maintained that with a properly constructed steam-vessel, there need be neither difficulty nor danger. The establishment of new routes for commerce, Commander Markham concluded, is always a gain to the science of geography. In come cases new regions have to be discovered and explored. In others the physical aspects of an already known region must be more carefully studied, and many points of interest relating to the action of climates, or of winds and currents, may be ascertained. The proposed Winnipeg and Hudson's Bay Railroad is a striking instance. The objections of opponents to the route have had to be carefully examined. All former experience had to be collected, maturely considered, and passed in review. Observatories had to be established at several points, to make certain whether the historical records actually coincided with physical facts as they now exist. The route itself had to be sailed over and explored. All these various researches have been as great a gain to geography as to commerce. They have enriched our science with a fresh stock of information, have revised previous conceptions, and confirmed or rejected, as the case may be, the theories and views which may have been put forward. From this point of view, and from this point of view alone, can commercial or political questions receive consideration here. The study of the Hudson's Bay route involves a problem for which physical geography alone can furnish a solution.

DR. F. H. H. GUILLEMARD has been recommended, by the joint Committee of the Royal Geographical Society and the University, as Lecturer on Geography at Cambridge.

THE *Bollettino* of the Italian Geographical Society for May publishes the map of the Massawa district (Massawa to Saati) prepared to the scale of 1 : 80,000, by Prof. P. Durazzo, with the materials which have been supplied by the Italian Staff officers during the recent military operations in that region. Prof. Durazzo has also now completed his large map in two sheets, scale 1 : 800,000, of all the Italian possessions and protectorates in East Africa. These cartographic works embody the results of all the latest surveys, and contain several new features, as well as some important corrections of existing maps.

OUR ELECTRICAL COLUMN.

THE beautiful illustrations of stress in a dielectric in an electric field, due to Dr. Kerr, have been modified and amplified by Messrs. Rücker and Boys, and were shown to a large audience at the Institution of Electrical Engineers on March 22, and again at the *soirée* of the Royal

Society. The dielectric they used was carbon bisulphide (CS_2), and the beam of light passed through about four inches of the liquid. The presence and intensity of the electric field was evident to all by the brightness of the screen. They showed experiments to illustrate the fact that the repulsion of similarly electrified bodies may be regarded as an attraction between each of them and surrounding objects. They have devised an experiment visible to a large audience to show that in an electric field the structure of the CS_2 becomes crystalline—that is, the optical properties along and transverse to the electric lines of force are different; in other words, the velocities of propagation of light vibrations differ when parallel and perpendicular to the lines of force, contrary to the view formerly held on the Continent that the effect is due to unequal expansion. They were able to increase the stress so that the liquid displayed colours even to the green of the second order; and by observing the spectrum of the light passing through the field, black bands enter at the violet end and traverse its whole length as the potential rises. Faraday's experiments and speculations, Maxwell's mathematics and theories, are rapidly becoming acknowledged facts; and the apparatus of Messrs. Rücker and Boys will materially assist in spreading a knowledge of the confirmation which those theories receive from the work of Kerr and Quincke.

BLONDLOT (*Comptes rendus*, January 30, 1888) has been working in the same direction, but with vibratory discharges from a Leyden jar, in order to test the existence or non-existence of retardation in the optical effects. He could see no retardation.

COWLES's process for the production of aluminium from its ores by the direct action of an electric current of 5000 amperes in an electric furnace has now become an industry. Works have been started near Stoke, and bronzes of wonderful quality are supplied at comparatively cheap prices.

THERE is a fashion in experimental investigation as in everything else. Self-induction is played out, and now the counter E.M.F. of the arc is passing through the same phase. Uppenborn (*Beiblätter*, No. 1, 1882, p. 83) is the last inquirer. He finds for a current of 7·7 amperes and 10 mm. carbons, that $a = 35{\cdot}4$ to $45{\cdot}4$; $b = 1{\cdot}74$ to $3{\cdot}2$ in Edlund's formula—

$$E = a + bl.$$

Since a decreases both for an increase of current and for an increase in the section of arc, he leans to a resistance hypothesis rather than an E.M.F.

KLEMENCIC (*Beiblätter*, No. 1, 1888, p. 57) finds the specific inductive capacity of mica to be 6·64; Cohn and Arons (*Ann. der Physik*, No. 1, 1888, p. 13) that of distilled water 76, ethyl alcohol 26·5, amyl alcohol 15, and petroleum 2·04.

PALMIERI (March 1888) has observed that in a bright clear sky, with a high and steady barometer, and every indication of continued fine weather, the electrometer will give an indication of change long before the barometer.

W. KOHLRAUSCH (*Electrotechnische Zeitschrift*, March 1888) has estimated the current and quantity of electricity in a lightning-flash. He calculates that it will take 9200 amperes to melt a copper rod of 2·5 centimetres diameter. Preece's constant (Proc. R.S., March 1888) makes it 10244. Such a current concentrated in a flash would contain from 52 to 270 coulombs, which would decompose from 5 to 25 milligrammes of water, and from 9 to 47 cubic centimetres of explosive gas. If this energy were stored up and distributed for electric lighting, it would require from 7 to 35 such flashes to keep one glow lamp alight for an hour.

VOGEL (*Electrotechnische Zeitschrift*, January 1888) had previously calculated the relative value of copper and iron as lightning-protectors, giving iron a section 2·5 times that of copper to act with equal efficiency. Preece's constants give the relative efficiency—

Iron	3148
Copper	10244

for equal diameters—that is, an inch rod will fuse with the above currents in amperes; or, if we take the same current, say 300 amperes—

Iron	0·2086
Copper	0·095

are the diameters in inches of the wires such currents will fuse, or in the ratio 2·2 to 1; Vogel's ratio being 13·54 to 9·6. Vogel did not consider the emissivity of the surface, and therefore his results are not so accurate as Preece's experimental figures.

THAT patient worker, H. Tomlinson, has proved that the temperature at which nickel begins to lose its magnetic properties is between 300° and 320° C.; but that the rate of decrease of magnetic permeability, and the temperature at which permeability practically vanishes, vary with the magnetizing force, and hence the widely different results by different observers. Faraday made the former point 330° to 340°; Becquerel 400°; Pouillet 350°; Chrystal 400°. Iron behaves in the same way: permeability vanishes between 750° and 770° according to Ledeboer.

PROF. EWING AND MR. COWAN have been examining the magnetic qualities of nickel on the same lines as the former examined iron. They confirm Sir W. Thomson's observation that longitudinal pull diminishes magnetism to a surprising extent. Their paper in the Philosophical Transactions will be looked forward to with much interest.

S. ARRHENIUS (*Wiener Berichte*, xcvi. p. 831) has shown that the electrical conductivity of chloride and bromide of silver was influenced by the intensity of the rays of light which fell upon the salts. It was most intense at G of the spectrum, and is therefore an effect of light, and not of heat.

F. KOHLRAUSCH (*Wiedemann's Annalen*, No. 4, 1888) has shown that the electric conductivity of

Hard steel	is 3·3
Soft steel	,, 5·5
Wrought iron	,, 7·6

mercury being 1; while their thermal conductivities in C.G.S. units were—

Hard steel	0·062
Soft steel	0·111
Wrought iron	0·152

the ratios being the same. Hence the conditions that determine the conduction of heat and electricity are the same.

MR. C. V. BOYS's interesting magnetic and electric experiments with soap-bubbles, and his wonderful manipulative skill, remind old *habitués* of the Royal Institution how exquisitely Faraday handled soap-bubbles blown with oxygen to illustrate the magnetic character of that gas. Mr. Boys blows one bubble inside another, and, on bringing the two into an electric field, the perfect indifference of the inner one to any change of potential clearly shows that electrification is confined to the absolute surfaces of a conductor, and that it is not felt at any depth within it, however small.

WHEAT CULTIVATION.[1]

THE most interesting sections of this number of the Journal are those bearing upon the subject of wheat cultivation. The permanent wheat and barley experiments at Woburn, reported upon by Sir John Lawes, Bart., is followed by a paper upon the condition of wheat-growing in India by Dr. George Watt, Reporter upon Economic Products to the Government of India. Next comes an article by Mr. W. E. Bear upon the Indian wheat trade. Lastly, in this connection, comes a highly interesting account of modern improvements in corn-milling machinery. These four papers occupy one-third part of the volume, and taken in connection with each other throw considerable light upon the difficulties under which the English wheat-grower is struggling. Dr. Watt and Mr. Bear both show the extraordinary extent of the wheat-producing area of our Indian Empire, and the rapidity with which this vast field is being opened up. With reference to the latter point men in middle life are scarcely likely to realize the fact that in 1853 there were in all only 20½ miles of railway in India, that in 1873 there were 5695 miles of railway, while in 1887 there were 13,386 miles. Telegraphic communication with India was first opened in 1865, and the opening of the Suez Canal in 1869 was scarcely of less importance in developing her trade—first, by shortening the passage, and secondly, by mitigating the risk from wheat weevil. Another agency has been the development of irrigation works.

[1] The Journal of the Royal Agricultural Society of England, vol. xxiv. (second series), part 1. (John Murray, Albemarle Street.)

We read that "only" 30,000,000 acres have up to date been artificially irrigated, but the appropriateness of the qualifying adverb is rendered evident when it is employed in contrast with the total area of 200,000,000 acres of cultivated ground, and the vast tract of 868,314 square miles which include British India. The normal area under wheat is 26,000,000 acres, and the degree to which this area is likely to be increased depends entirely upon demand and price. Dr. Watt informs us that the Indian cultivator is at all times ready to adapt his courses of cropping to circumstances, and that he will increase or abandon the cultivation of wheat, cotton, or any other crop according to its comparative profitableness.

Dr. Watt comes to the conclusion that the Indian wheat trade up to the present time is a perfectly natural one. "The people are exporting only what they specially cultivate for that purpose. The moment better profits can be realized on another crop they will turn from wheat, without being in the least degree incommoded." If this is the case, the English farmer may well look with envy upon his Indian brother, as he is in the unfortunate position of being compelled to carry on wheat-growing from sheer inability to find a substitute for it in his agricultural economy. Natural though the course of the ryot may be from his point of view, the actual bounty upon wheat, or what amounts to a bounty, consequent upon the fall in value of the rupee, can scarcely be described as natural. This great advantage to the Indian cultivator is clearly brought out by Mr. Bear by the following considerations. First, the Indian ryot gets as much for a quarter of his wheat now as he obtained in 1872. He gets as many rupees, and his rupees are worth as much to him as they were then! In 1871-72 the average exchange value of the rupee was 1*s.* 11·12*d.*, whereas recently it has been under 1*s.* 5*d.* The price of No. 2 club wheat in Calcutta in 1872 averaged only 2*rs.* 3*a.* 1*p.* per maund, whereas it has for some time past been over 2*rs.* 10*a.*! Taking 16*rs.* per quarter (6 maunds) as the price for both periods, then reckoning the exchange value of the rupee for both periods, it is clear that the exchange value of 16*rs.* in 1872 was equal to 30*s.* 8*d.* per quarter, whereas the exchange value of the same sum in 1888 is only 22*s.* 8*d.* The fact is that the Indian ryot gets as much for a quarter of wheat now as he did in 1872, in spite of the fall in prices. He gets as many rupees, *and his rupees are worth as much to him.* This seems to settle the question as to the encouragement given to the ryot as a competitor in wheat-growing with the English farmer. Another point, in all respects discouraging to the cultivation of wheat in England, is found in the complete revolution during the last ten years in corn-milling machinery described by Mr. W. Proctor Baker, of Bristol. There has been in fact not a mere substitution of one machine for another, or of one series of machines for another, but there has been a change of the principle and mode of procedure. The old system of "low grinding" by mill-stones, so well calculated for producing flour from soft, tender wheats, such as are produced by us, has been entirely superseded by the Hungarian and American "gradual reduction" process by "roller mills." Not only does this system require the wheat to be dry, hard, and brittle, so as to secure the requisite cracking and gradual reduction, but anything in the form of a soft or moist wheat is most injurious to the machinery and the products. It rolls into a paste, steam is generated, and the flour works into balls, becomes attached to the rollers, turns sour, and, in fact, throws the entire process out of gear. "It is because of these troubles that owners of mills on a large scale will not employ native wheats in damp seasons. No concession of price is sufficient inducement to them to risk the disorganization of the mill, and probable loss of reputation, by turning out inferior or irregular flour." There are, however, two modes in which these wheats may be used. First, by submitting them to an artificial drying process; and secondly, by mixing them with some description of very brittle wheat, and allowing the mixture to lie for some weeks, until the brittle wheat absorbs some of the moisture of the native wheat, to the mutual advantange of both.

One of the most serious points at issue between science and agricultural practice at present appears to be the comparative values of farm-yard manure and artificial fertilizers. So far as absolute experiment goes, the evidence seems to be in favour of the application of the latter, while, on the other hand, the preponderating opinion among farmers is on the side of farm-yard manure. In the Report on the Field and Feeding Experiments at Woburn, by Dr. J. Augustus Voelcker, applications of dung appear somewhat at a disadvantage when contrasted with applications of salts of potash, phosphates, and nitrates direct. Mr. Vallentine, in his paper upon the practical value of dung as compared with artificial manures, declares in favour of the latter, and labours to show the extravagant cost at which farm-yard manure is produced. "For years past," he says, "my main reliance has been placed on artificial manures. Some dung is made and some bought, but it is found to answer best, as a rule, to sell hay and straw and to purchase manures." This may answer on some classes of soil; but what would be the effect upon our high-lying and thin chalk downs if we were to relinquish sheep-farming and depend upon "artificials?"

Many more valuable papers well repay perusal, among others one upon recent experiences in laying land down to grass, by Mr. James A. Caird. The remainder are mostly official in character, being the usual Reports upon implements, prize farm competitions, shows, experiments, and the Annual Reports of the Consulting Chemist, Botanist, and Entomologist, which, however, are none the less valuable for being official.

Downton. JOHN WRIGHTSON.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following are the speeches delivered on June 9 by the Public Orator, Dr. Sandys, Fellow and Tutor of St. John's College, in presenting for the honorary degree of Doctor in Science, Prof. G. G. Stokes, Lord Rayleigh, Sir Frederick Abel, Prof. Cayley, and Prof. Adams:—

(1) Salutamus deinceps Regiae societatis praesidem, professorem nostrum Lucasianum, senatorum nostrorum omnium consensu Britanniae senatoribus additum; quem in munere illo triplici Newtoni nostri in vestigiis insistere gloriamur. Atqui ipse, qua est morum suavitate et modestia, vix tali sese honore dignatur, sed a plausu populari remotus et seclusus, templum quoddam serenum occupat, ubi reverentia debita rerum naturae miracula perscrutatur, ubi "in statione tranquilla collocatus" lucis leges obscuras observat, observatas ingenii sui lumine illustrat. Viro tali rerum naturam contemplanti crediderim apparere nonnunquam sedes illas quietas,

> "quas neque concutiunt venti, nec nubila nimbis
> aspergunt, neque nix acri concreta pruina
> cana cadens violat, semperque innubilus aether
> integit, et large diffuso lumine ridet."

Duco ad vos virum illustrem, PROFESSOREM STOKES.

(2) Venio ad nomen physicorum professoris quem non sine desiderio nuper amisimus, viri cum Cancellarii nostri munificentia haud ita pridem consociati. Ex illo velut fonte, liberalitatis flumen amplum professoris nostri in provinciam defluxit inque alias Academiae partes redundavit. Ipse fontium exsilientium et aquarum destillantium naturam quam feliciter exploravit; caeli colorem illum caeruleum quam dilucide explicuit; quicquid audiendi quicquid videndi ad rationes intimas pertinet, quam sapienter interpretatus est; quotiens in rerum natura eventis specie quidem inter sese diversis causas easdem subesse ostendit. Quam profundam rei mathematicae θεωρίαν, ut aiunt, cum quanta in experimentis instituendis sollertia coniunxit; quam subtilem denique scientiae cognitionem cum sensu illo communi consociavit qui non in magna tantum fortuna sed in omni vitae condicione rerum omnium est revera ra rissimus.

Duco ad vos IOANNEM WILELMUM STRUTT, BARONEM RAYLEIGH.

(3) Scientiam Chemicam et in bello et in pace utilem esse, quis negabit? Heri in hoc ipso loco virum hunc insignem docentem audivistis, quo potissimum modo scientia illa populi saluti consulere et pericula pacis in artibus suscepta possit avertere. Idem Martis fulmina illa antiquis ignota quam familiariter tractat: pulverem illum formidolosum quo Bellona gaudet, quot experimentis vexat: quam admirabilem in modum velut Olympius ille Aristophanis, fulgurat, tonat, omnia permiscet. Atqui non minus quam Pericles ille Atheniensis, qui tot insularum imperium civitati suae conciliavit, inter ipsa tonitrua audit tot coloniarum Britannicarum uno in imperio coniunctarum vocem, et illorum consiliis pro virili parte op'tulatur qui in ipsa μητροπόλει artium et scientiarum templum quoddam tanto imperio dignum consecrare voluerunt. Templi illius e sacerdotibus unum, cuius praeceptor coram Principe nostro in hoc senaculo quondam

laudatus est, hodie coram eodem, templi illius praeside illustrissimo, titulo nostro libenter ornamus.

"sunt hic etiam sua praemia laudi;
sunt lacrimae rerum et mentem mortalia tangunt."

Duco ad vos Hofmanni discipulum, Faradai successorem, FREDERICUM AUGUSTUM ABEL.

(4) Perveni tandem ad Professorem nostrum Sadlerianum, virum non modo in recentioris quae dicitur Algebrae provincia, sed etiam studiorum mathematicorum in toto regno inter principes numeratum; qui, quamquam iuris peritia honores summos adipisci potuisset, maluit sese scientiae illi dedicare, quae verbis quam paucissimis, quam illi quae verbis quam plurimis, rerum veritatem exprimere conatur. Quantum tamen prudentia eius Academiae profuerit, et senatus totius concilium et Collegium plus quam unum testantur; neque Cami tantum prope ripas sed etiam in ipsa Europa atque adeo trans aequor Atlanticum fontes eius aliis patuerunt. Idem, velut alter Socrates, ipsi rerum pulchritudini et veritati mentis oculis contemplandae sese consecravit, arbitratus illa sola quae studiorum suorum in puro velut caelo sint, revera esse, illorum autem imagines quas φαινόμενα vocamus, velut specus εἴδωλα videri; ipsam vero pulchritudinem percipi quidem posse sed non omnibus explicari. Quam dilucide tamen regnum suum quondam non campo deserto comparavit sed regioni cuidam pulcherrimae primum e longinquo prospectae, cuius partem unamquamque posse deinde peragrari, cuius et clivos et valles, et rivos et rupes, et flores et silvas posse propius maxima cum voluptate aspici. Diu, inter numina silvestria, regionem illam laetam feliciter pererret Professor noster insignis, ARTHURUS CAYLEY.

(5) Extra ipsas Athenas, stadiis fere decem ab urbe remotus, prope ipsam Platonis Academiam, surgit Coloneus ille tumulus Sophocleo carmine olim laudatus, Neptuni templo quondam ornatus, astronomi magni Metonis cum memoria consociatus. Et nos Colonum nostrum iactamus, clivum illum spatio a nobis eodem distantem, locum arboribus obsitum, avibus canorum, ubi in templo quodam stellis observandis dedicato vivit Neptuni ipsius inventor. Quid si Colono nostro deest Cephisus? sed aqua de clivo illo antiquitus deducta, Collegii Herscheliani sub hortis transmissa, Newtoni in Collegio in fontem exsilit. Quid si Neptuni inventi gloria cum altero participatur? sed, gloriae illius geminae velut imago perpetua, Geminorum in sidere est stella quaedam quae caeli totius inter stellas duplices prae ceteris fulget. Idem neque stellarum geminarum cursus, neque Saturnum neque Uranum inexploratum reliquit; neque faces illas caelestes, Leonides vocatas, quas ter in annis fere centenis orbes suos magnos conficere ostendit; neque motum illum medium lunae qui cum motu diurno terrae collatus per saeculorum lapsus paullatim acceleratur. Talium virorum laudibus non debet obesse quod inter nosmet ipsos vivunt; pravum enim malignumque foret "non admirari hominem admiratione dignissimum, quia videre, alloqui, audire, complecti, nec laudare tantum, verum etiam amare contigit."

Tot insignium virorum nominibus hodie velut cumulus accessit vir illustris, PROFESSOR ADAMS.

The Senior Wrangler of the year is Mr. Orr, of St. John's; the Second Wrangler Mr. Brunyate, of Trinity. No woman is placed with the Wranglers; but one, Miss H. F. Ashwin, of Girton, is bracketed with the first Senior Optime.

The Rede Lecture was delivered in the Senate House on Friday, by Sir F. A. Abel, on the applications of science to the protection of human life.

The Report on Local Lectures gives particulars of a large number of science lectures given in local populous centres. At evening lectures on astronomy at Northampton, Mr. J. D. McClure had a regular audience of 277, and 250 at Aylesbury. The formation of Students' Associations, for mutual aid between the lectures, has been very useful. Several students from Northumberland came up to Cambridge in the Long Vacation, and did practical work in chemistry and biology.

The Syndicate appointed to report on Sir Isaac Newton's manuscripts in the possession of the Earl of Portsmouth, the scientific portion of which he offered to present to the University, have prepared a detailed catalogue of the whole, which is to be published.

Prof. Thomson announces that students who receive permission may work in the Cavendish Laboratory in the Long Vacation. There will be a special course for those who have passed the Mathematical Tripos, and intend taking the Natural Sciences Tripos.

In the Long Vacation, Mr. Fenton will give a general course on Chemistry, Mr. Potter will lecture on Systematic Botany with practical work, Prof. Macalister will lecture on Osteology, and Mr. Wingfield will give a revision course of Practical Physiology for Dr. Foster; Prof. Roy will lecture on the Elements of Pathology, and will hold a practical course on three days a week.

Prof. Lewis will lecture on Crystallography during July, and Mr. Solly will give elementary demonstrations in Mineralogy during July and August.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. x. No. 3 (Baltimore, April).—The number opens with an article by M. E. Goursat, "Surfaces telles que la somme des rayons de courbure principaux est proportionnelle à la distance d'un point fixe au plan tangent" (pp. 187–204), in which are discussed some surfaces of a somewhat more general character than those treated of by M. Appell in the last number of the *Journal*. The title sufficiently indicates the scope of the memoir, which in part touches upon work accomplished by Riemann.—"Remarks on the Logarithmic Integrals of Regular Linear or Differential Equations" (pp. 205–24), by Karl Heun, follows up Fuchs's investigations (*Journal für Mathematik*, lxviii. p. 376). The author has elsewhere shown that the Fuchs equations are not independent of each other when the differential equation is of a higher order than the second, and in this paper he deduces, from elementary considerations, the minimum number of conditions on which the existence of logarithms depends. In addition he gives several theorems concerning the pseudo-singular points.—Mr. C. H. Chapman, in his article "On Some Applications of the Units of an n-fold Space" (pp. 224–42), obtains a proof of the rule for multiplying two determinants of the nth order by the principles of quaternions.—In "A Problem suggested in the Geometry of Nets of Curves and applied to the Theory of Six Points having Multiply Perspective Relations" (pp. 243–57), Mr. E. H. Moore discusses matters treated of by Von Staudt, Clebsch, Klein, and others.—Adopting the definition of *orientation* given by Laguerre, M. G. Humbert generalizes results previously obtained by Laguerre and himself in a memoir entitled "Sur l'orientation des systèmes de droites" (pp. 258–81), and also brings together some interesting properties of the hypocycloid given already by Cremona and Darboux.

Bulletin de l'Académie Royale de Belgique, April.—Contribution to the study of the albuminoid substances in the white of an egg, by MM. G. Corin and E. Bérard. It was recently shown by Halliburton that the albumen of the serum is a mixture of two or of three albumens, according to the nature of the animal, which coagulate under different degrees of temperature. Applying the same process of research to the albuminoids of the white of eggs, the authors find that five different albuminoid substances are present in this liquid: two globulines, coagulating at $+57°$ and $+67°$ C. respectively, and three true albumens, coagulating at $+72°$, $+76°$, and $+82°$. Besides these new facts, they also offer some interesting remarks on the general character of the relations existing between the albumens and the globulines, and on the opalescence observed when these substances begin to coagulate under the action of heat.—M. F. Folie describes a new method of determining the constant of aberration by means of a series of observations of one and the same star in right ascension. For this method he claims great simplicity, and exemption from the numerous sources of error to which other processes are liable.—To this number of the *Bulletin*, A. F. Renard contributes an exhaustive memoir on the prevailing geological formations of the Cape Verd Islands.

Rendiconti del Reale Istituto Lombardo, May.—On an old theory regarding the climate of Quaternary times, by Prof. T. Taramelli. Reference is made to the theory announced in 1840 by Lombardini, who considered that the Quaternary climate was simply a continuation of those of previous epochs, modified by the appearance of more elevated lands upheaved in post-Tertiary times. This anticipates by twenty years Frankland's remarks on the physical causes of the Glacial epoch, and leads the author to formulate a vulcanico-glacial theory based on the views of these physicists and of Charpentier.—Meteorological observations made at the Brera Observatory, Milan, during the month of April.

Rivista Scientifico-Industriale, May 15.—Remarks on the earthquake at Florence on November 14, 1887, by Prof. P. G. Giovannozzi. Following the system adopted by Serpieri, the author has collected data from various quarters showing that the disturbance was of a purely local character. The chief shock, although so violent as to have been heard by the deaf, passed through the city with such velocity that very little damage was done. It presented all the characters of a true gaseous explosion, taking a vertical direction from a moderate depth below the crust of the earth, and absolutely unconnected with any volcanic phenomena. It is noteworthy that the earthquake followed a long and exceptional period of wet weather, during which a rainfall of 225mm. was recorded within the zone of disturbance.

SOCIETIES AND ACADEMIES.

London.

Royal Society, May 17.—"On Æolotropic Elastic Solids." By C. Chree, M.A., Fellow of King's College, Cambridge. Communicated by Prof. J. J. Thomson, F.R.S.

On the multi-constant theory of elasticity, the equations connecting the strains and stresses contain 21 constants. As shown by Saint-Venant, these reduce for one-plane symmetry to 13, for three-plane symmetry to 9, and for symmetry round an axis perpendicular to a plane of symmetry to 5.

Part I. of this paper deals with one-plane symmetry. A solution is obtained of the internal equations of equilibrium complete so far as it goes. It is employed in solving the problem, already treated by Saint-Venant, of a beam, whose length is perpendicular to the plane of symmetry, held at one end, and at the other acted on by a system of forces, whose resultant consists of a single force along the axis of the beam, and of a couple about any line in the terminal section through its centroid. The case when the cross-section is elliptical, and the beam exposed to equilibrating torsional couples over its ends is also treated. Results are obtained confirmatory of Saint-Venant's. They are also extended to the case of a composite cylinder, formed of shells of different materials whose cross-sections are bounded by concentric similar and similarly situated ellipses, the law of variation being the same for all the elastic constants of the solution. The limiting case of a continuously varying structure is deduced.

When a beam of circular section is exposed to torsion, it is proved that warping will ensue proportional to the moment of the twisting couple. Only two diameters in the cross-section, and these mutually at right angles, remain perpendicular to the axis of the beam.

Part II. treats of a material symmetrical round an axis, that of z, and having the perpendicular plane one of symmetry. A general solution of the internal equations of equilibrium is obtained, supposing no bodily forces to act. The solution involves arbitrary constants, and consists of a series of parts, each composed of a series of terms involving homogeneous products of the variables, such as $x^l y^m z^{n-l-m}$, where l, m, n are integers, and n is greater than 3. The terms involving powers of the variables, the sum of whose indices is less than 4, are then obtained by a more elementary process, and these alone are required in the applications which follow.

The first application of the solution is to "Saint-Venant's problem" for a beam of elliptical cross-section. The problem is worked out without introducing any assumptions, and a solution obtained, which is thus directly proved to be the only solution possible if powers of the variables above the third be neglected.

Part III. consists of an application of the second portion of the solution of Part II. to the case of a spheroid, oblate or prolate, and of any eccentricity, rotating with uniform angular velocity round its axis of symmetry, which is also the axis of symmetry of the material. The surface of the spheroid is supposed free of all forces.

The limiting form of the solution, when the polar axis of the spheroid is supposed to diminish indefinitely, is applied to the case of a thin circular disk rotating freely about a perpendicular to its plane through its centre. The solution so obtained is shown to satisfy all the conditions required for the circular disk, except that it brings in small tangential surface stresses. According to this solution the disk increases in radius, and diminishes everywhere in thickness, especially near the axis, so as to become biconcave. All, originally plane, sections parallel to the faces become very approximately paraboloids of revolution.

Again, by supposing the ratio of the polar to the equatorial diameter of the spheroid to become very great, a surface is obtained which differs very little from that of a right circular cylinder. The corresponding form of the solution obtained for the spheroid, when the ratio of the polar to the equatorial diameter becomes infinite, may thus be expected to apply very approximately to a long thin cylinder. This is verified directly, and it is shown that this solution is in all respects as approximately true as that universally accepted for Saint-Venant's problem. According to the solution the cylinder shortens, and every cross-section increases in radius but remains plane.

Part IV. treats of the longitudinal vibrations of a bar of uniform circular section and of material the same as in Part II. Assuming strains of the form—

$$\text{radial} = r\psi(r)\cos(pz - \alpha)\cos kt,$$
$$\text{longitudinal} = \phi(r)\sin(pz - \alpha)\cos kt,$$

$\phi(r)$ is found in terms of $\psi(r)$ by means of the equations established in Part II. From these equations is deduced a differential equation of the fourth order for $\psi(r)$, and for this a solution is obtained containing only positive integral even powers of r. A relation exists, determining all the constants of the solution in terms of the coefficients a_0 and a_2 of r^0 and r^2. In applying this solution to the problem mentioned, terms containing powers of r above the fourth are neglected, and it is shown to what extent the results obtained are approximate.

On the curved surface, the two conditions that the normal and tangential stresses must vanish lead to the following relation between k and p—

$$k = p\left(\frac{M}{\rho}\right)^{\frac{1}{2}}\{1 - \tfrac{1}{4}p^2a^2\sigma^2\}.$$

Here ρ denotes the density and a the radius of the beam, while M is Young's modulus, and σ the ratio of lateral contraction to longitudinal expansion for terminal traction. This agrees with a result obtained by Lord Rayleigh ("Theory of Sound," vol. i. § 157) on a special hypothesis.

Proceeding to the terminal conditions, it is shown how p is determined from the conditions at the ends. Since a_0 depends only on the amplitude of the vibrations, we are left with no arbitrary constant undetermined. If the bar be so "fixed" at its ends that the radial motion is unobstructed, this leads to no difficulty, but if an end be "free" a difficulty arises. At such an end the solution requires the existence of a radial stress $\propto (2i + 1)^3 r (a^2 - r^2)/l^3$, where i is an integer depending on the number of the harmonic of the fundamental note, and l denotes the length of the bar. There will thus be a difference in these cases between the results of experiment and those of the accepted theory, even as amended by Lord Rayleigh. This divergence will increase rapidly with the order of the harmonic, and, though very small for a long thin bar, will increase rapidly as the ratio of the diameter to the length is increased. Since, in dealing with the conditions at the curved surface, terms of the order $(a/l)^5$ were neglected, the same remarks apply, though to a smaller extent, in the case of the "fixed-fixed" vibrations.

May 31.—"Investigations on the Spectrum of Magnesium. No. II." By Profs. Liveing and Dewar.

Since our last communication on this subject, we have made many additional observations on the spectrum of magnesium under various circumstances, and have arrived at some new results. Speaking generally, we find that differences of temperature, such as we get in the flame of burning magnesium, in the arc, and in the spark, produce less differences in the spectrum than we had before attributed to them. For instance, the lines which previously we had observed only in the spark discharge, we have since found to be developed in the arc also, provided the discharge occur between electrodes of magnesium.[1] In making these experiments we used thick electrodes of magnesium, and brought them together inside a glass globe about 6 inches in diameter, fitted with a plate of quartz in front

[1] Compare the appearance of the lines of hydrogen in the arc discharge. Roy. Soc. Proc., vol. xxx. p. 157; and vol. xxxv p. 75.

and filled from time to time with various gases. The arc was an instantaneous flash which could not be repeated more than twice without rendering the sides of the vessel opaque with a complete coating of magnesium. It was therefore analogous to an explosion of magnesium vapour. The strong blue line λ4481, two pairs about λ3895, 3893, and λ3855, 3848, the strong pair about λ2935, 2927, and the two weaker lines of the quadruple group, namely λ2789·9 and 2797, all come out in the arc given by a Siemens dynamo between magnesium electrodes in air, in nitrogen, and in hydrogen. We have observed most of them also when the arc is taken in carbonic acid, in ammonia, in steam, in hydrochloric acid, in chlorine, and in oxygen. The observations render doubtful the correctness of the received opinion that the temperature of the spark discharge is much higher than that of the arc. Heat, however, is not the only form of energy which may give rise to vibrations, and it is probable that the energy of the electric discharge, as well as that due to chemical change, may directly impart to the matter affected vibrations which are more intense than the temperature alone would produce.

The Bands of the Oxide.

The set of seven bands in the green, beginning at about λ5006·4 and fading towards the violet side of the spectrum, which we have before attributed to the oxide of magnesium, have been subjected to further observation, and we have no reason to doubt the correctness of our former conclusion that they are due either to magnesia or to the chemical action of oxidation. On repeating our experiments with the spark of an induction coil between magnesium electrodes in different gases at atmospheric pressure, we could see no trace of these bands in hydrogen, nitrogen, or ammonia, whether a Leyden jar was used or not. Nor could we see them at all in carbonic oxide, but in this case the brightness of the lines due to the gas might prevent the bands being seen if they were only feebly developed. On the other hand, the bands come out brilliantly when the gas is oxygen or carbonic acid, both with and without the use of a Leyden jar. In air and in steam they are less brilliant, but may be well seen when no jar is used. When a jar is used they are less conspicuous, because in air the lines of nitrogen come out strongly in the same region, and in steam the F line of hydrogen becomes both very bright and much expanded.[1] It seems, therefore, that it is not the character of the electric discharge, but the nature of the gas which determines the appearance of the bands; and the absence of the bands in the absence of oxygen, and their increased brilliance in that gas, leave little room for doubt that they are due to the oxide, or to the process of oxidation. If a very small piece of magnesia, such as a fragment of the ash of burnt magnesium ribbon, be held in an oxy-hydrogen jet, most of the spectrum of burning magnesium is developed in the flame for a short distance from the piece of magnesia. Under these circumstances, the flame shows the *b* group and the magnesium-hydrogen series close to it, the bands in the green, the triplet near L, the triplet near M of the flame of burning magnesium, with the group of bands in that region, and the line λ2852. It is remarkable that the proportions in which the oxygen and hydrogen are mixed affect the relative intensities of different parts of the spectrum. In general, both the metallic lines of the *b* group and the bands of the oxide are easily seen; but if the oxygen be in excess the bands of the oxide come out with increased brightness, while the *b* group fades or sometimes becomes invisible. On the other hand, if the hydrogen be in excess the bands fade, and the *b* group shows increased brilliance. There can hardly be much difference in the temperature of the flame according as one gas or the other is in excess, but the excess of oxygen is favourable to the formation and stability of the oxide, while excess of hydrogen facilitates the reduction of magnesium and its maintenance in the metallic state. As regards temperature, it should be observed that while substances merely heated by the flame, and not undergoing chemical change, are not likely to rise to a temperature above the average temperature of the flame, it will be otherwise with the materials of the flame itself and other substances in it which are undergoing chemical change, and have at the instant of such change the kinetic energy due to the change.

[1] Neither the arc of a Siemens dynamo, nor that of a De Meritens magneto-electric machine, when taken in a crucible of magnesia, shows these bands, even if metallic magnesium be dropped into it. A stream of hydrogen led into the crucible with a view to cool it does not elicit them. When the arc is taken in the open air, and metallic magnesium dropped through it, the bands appear momentarily, but that is probably the result of the burning of the magnesium vapour outside the arc. (May 23.)

In fact, when chemical changes are occurring in a flame it cannot be taken for granted that the temperatures of the molecules are all alike, or that the vibrations which they assume are the result of heat alone. On the other hand, the temperature of the metal separated from magnesia by the oxyhydrogen flame cannot, we suppose, be at a temperature higher than that of the hottest part of the flame. We are therefore inclined to think that the metallic lines (*b*) are manifested at a lower temperature than the bands of the oxide; and the appearance of a line in the position of the first band without any trace of the second band (which is nearly as bright as the first), and without any trace of the *b* group, is quite sufficient to create a suspicion of mistaken identity when Mr. Lockyer ascribes the sharp green line in the spectrum of nebulæ to this band of magnesia. This suspicion will be strengthened when it is noticed that the line in question is usually in the nebulæ associated with the F line of hydrogen, if it be borne in mind that the spark of magnesium in hydrogen does not give the bands, and that the oxyhydrogen flame hardly produces them from magnesia when the hydrogen is in excess.

In Mr. Lockyer's map of the spectrum of the nebula in Orion (Roy. Soc. Proc. vol. xliii. p. 134), he has represented three lines in the position of the edges of the first three of these bands. If these three lines were really seen in the nebula, there would be less room to doubt the identity of the spectra; but the authorities quoted for the map (*loc. cit.*, p. 142) mention only a single line in this position.

When the flame of burning magnesium is viewed with a high dispersion, these bands are resolved into series of fine, closely set lines. Seven such series may be counted, beginning at the approximate wave-lengths 5006·4, 4995·6, 4985·4, 4973·6, 4961·6, 4948·6, 4934·4, respectively. When a condensed spark is taken between magnesium electrodes in oxygen mixed with a little air, the pair of strong nitrogen lines may be seen simultaneously with the bands, and lying within the first band, the bright edge of the band being somewhat less refrangible than the less refrangible of the two nitrogen lines.

When the bands are produced by the spark discharge between magnesium electrodes in oxygen or other gas, we have not been able to resolve them into lines, but the whole amount of light from the spark is small compared with that from the flame, and besides it is possible that the several lines forming the shading may be expanded in the spark, and thus obliterate the darker spaces between them.

Triplet near M and adjacent Bands.

Our former account of the spectrum of the flame of burning magnesium included a description of a triplet near the solar line M, and a series of bands extending from it beyond the well-known triplet near L. As we had not observed these features in the spectrum of the spark or arc, and could not trace their connection with any compound, we concluded that they were produced by magnesium only at the comparatively low temperature of the flame. We have since found that they are not produced by the metal at that temperature only, but are exhibited as strongly, or even more strongly, in the arc between electrodes of magnesium. In the latter case they appear concurrently with the line at 4481 and other lines which seem to belong to high temperatures. We must therefore regard them as not only produced at the temperature of flames, but as persistent at temperatures very much higher.

The different circumstances under which we have observed this triplet are as follow:—

In the oxyhydrogen flame when a very small piece of magnesia is held in it. In this case the outer two lines of the triplet are much stronger than the middle line (λ3724 about), which in some of our photographs does not show at all. It should be noticed that the least refrangible of the three lines (λ3730 about) is in general more diffuse and not quite so bright as the two more refrangible lines. Magnesia in the oxyhydrogen flame also gives rise to some bands close to and more refrangible than the triplet, and to another still more refrangible but less bright triplet, in which the lines are set at nearly equal distances from each other, with the approximate wave-lengths 3633·7, 3626·2, 3620·6. These additional bands and triplets are not really absent from the flame spectrum, for traces of them may be seen in some of our photographs of the magnesium flame, but they seem relatively brighter in the oxyhydrogen flame with magnesia, and the longer exposure of the photographic plate in the latter case helped to bring them out. They seem to come out more strongly under the conditions which make both the green bands of the oxide and the *b* group show well.

We have not noticed the more refrangible triplet (λ3633·7 to 3620·6 about) under other circumstances, but the triplet near M is produced when magnesia is held in the flame of cyanogen burning in oxygen, in the flash of pyroxylin with which magnesium filings have been mixed, or which has been treated with an alcoholic solution of magnesium chloride.

It is not only very strongly developed, but shows strongly reversed on our photographic plates, in the spectrum of the arc from a Siemens dynamo taken between electrodes of magnesium in oxygen; and most of the accompanying ultra-violet bands of the magnesium flame spectrum are at the same time reversed. It is less strongly, but distinctly, reversed in the spectrum of the same arc taken in air, in carbonic acid gas, and in sulphurous acid gas. It appears also if the arc is taken in ordinary nitrogen unless great precautions are taken to exclude all traces of oxygen or carbonic acid, when it completely disappears. It is developed also in the flash produced when a piece of magnesium ribbon is dissipated in air by the discharge through it of the current from 50 cells of a storage battery. Also in the spark in air at atmospheric pressure between magnesium electrodes connected with the secondary wire of an induction coil when the alternating current of a De Meritens magneto-electric machine is passed through the primary.

In two cases, but only two, we have found this triplet, or what looks like one or both of the more refrangible of its lines, developed in vacuous tubes. In both tubes the gas was air. One had platinum electrodes and a strip of magnesia from burnt magnesium disposed along the tube; the other had fragments of the Dhurmsala meteorite attached to the platinum electrodes. The discharge was that of an induction coil worked in the usual way without a Leyden jar. In each case it is only in one photograph of the spectrum that the lines in question appear. In other photographs taken with the same tubes they do not show.

On the other hand, this triplet does not make its appearance in the arc from a dynamo between magnesium electrodes in hydrogen, coal gas, cyanogen,[1] chlorine, hydrochloric acid, or ammonia; nor in the arc from a De Meritens machine in hydrogen or nitrogen. It does not show in the spark between magnesium electrodes of an induction coil used in the ordinary way, either with or without a Leyden jar, in hydrogen or in air at atmospheric pressure; nor in the glow discharge in vacuous tubes with magnesium electrodes when the residual gas is either air, oxygen, hydrogen, carbonic acid gas, or cyanogen. Nor does it appear, except in the one instance above-mentioned, in the glow discharge in highly rarefied air in a tube containing either magnesia or a strip of metallic magnesium.

A review of all the circumstances under which the triplet near M and its associated bands appear, and of those under which they fail to appear, leads pretty conclusively to the inference that they are due not to merely heated magnesium but to the oxide, or to vibrations set up by the process of oxidation.

We have expended a vast amount of time and trouble over vacuous tubes, and our later experiments do but confirm the opinion which we had previously formed that there is an uncertainty about them, their contents and condition, which makes us distrustful of conclusions which depend on them. Photographs of the ultra-violet spectra given by such tubes tell tales of impurities as unexpected as they are difficult to avoid. Every tube of hydrogen which we have examined exhibits the water spectrum more or less, even if metallic sodium has been heated in the tube, or the gas dried by prolonged contact with phosphoric oxide. Indeed the only tubes which do not show the water spectrum have been filled with gases from anhydrous materials contained in a part of the tube itself; and even when tubes have been filled with carbonic acid gas from previously fused sodium carbonate and boracic anhydride the water spectrum is hardly ever absent. The last traces of the ultra-violet bands of nitrogen are almost as difficult to be rid of with certainty. Frequently, unknown lines or bands make their appearance, and the same tube will at different times exhibit wholly different spectra. This is especially the case with tubes of rarefied gases which oppose much resistance to the passage of the electric discharge, such as oxygen.

[1] In taking the arc in this way in cyanogen our photographs show the whole of the five bands of cyanogen between K and L well reversed. We have before noticed (Roy. Soc. Proc., vol. xxxiii. p. 4) the reversal of the more refrangible three of these bands against the bright background of the expanded lines of magnesium when some of that metal was dropped into the arc between carbon electrodes, but in taking the arc between magnesium electrodes in an atmosphere of cyanogen the bright wings of the expanded magnesium lines near L extend beyond the cyanogen bands, and the whole series of the latter are well reversed. (May 23.)

The ultra-violet magnesium lines which we have observed in vacuous tubes with magnesium electrodes, when the induction coil, without jar, is employed, are the triplets at λ3837, and the lines λ2852, 2802, and 2795. These appear whether the residual gas be air, oxygen, hydrogen, or carbonic acid. When a jar is used we have obtained also the triplets at P and S, the pair about λ2935 and 2927, and the quadruple group near λ2802 and the quintuple group beyond, and *in one case only*, in oxygen, the group near *s*, described below, and the flame-triplet near M. When no jar is used sometimes only λ2852 is to be seen, sometimes λ2852 and the strong pair near λ2802, and sometimes also the triplet near L. We infer, therefore, that this is the order of persistency of these lines under the circumstances.

Group near "s."

In their list of lines in the spectrum of magnesium (Phil. Trans., 1884, p. 95) Messrs. Hartley and Adeney have given two lines, λ3071·6 and λ3046·0, which we had not heretofore observed either in the spectrum of the flame, arc, or spark of magnesium; but in our recent observations we have noticed in many cases a well-marked line which, by interpolation between neighbouring iron lines, appears to have a wave-length about 3073·5, and a pair of narrow bands sharply defined on their less refrangible sides at wave-lengths about 3050·6 and 3046·7, and fading away on their more refrangible sides.

The circumstances under which this group is seen and is not seen, do not seem to indicate that its emission is connected with any particular temperatures so much as with the character of the electric discharge, and perhaps also with the density of the magnesium vapour.

Royal Microscopical Society, May 9.—Dr. C. T. Hudson, President, in the chair.—The President said that on the occasion of his taking the chair for the first time, he desired, before beginning the business of the evening, to thank the Fellows very heartily for the honour which they had done him in electing him their President.—Mr. Crisp exhibited a form of camera lucida by M. Dumaige, of Paris, fitted in a box with a cover, which, when closed, kept the prism and mirror free from dust; also by the same maker, an adapter with spiral springs, for rapidly changing objectives, and a portable microscope in which the foot and stage were in one piece.—Dr. Kibbler exhibited and described a new stand and camera, which, he believed, would be found very useful for photomicrography. It had been made to his design by Mr. Bailey, his idea being that it was best not to take negatives upon a large plate, but on a quarter-plate first, and afterwards to enlarge the pictures from the original negatives. The great advantage of this method was in the amount of light gained for the purpose of focussing. The quarter-plate size was also the proper one for lantern slides. The ordinary diaphragm plate placed immediately below the stage he had found entirely useless, but by removing it a certain distance from the object it then ceased to cut off the field, and began to reduce the light and to improve the penetration and definition. With high powers this answered very well, but it would not work with low powers unless the diaphragm was removed to a distance too great to be convenient in practice. He had therefore devised the plan of introducing a short 1½-inch condenser behind the stage, and about 3 inches in front of the diaphragm plate, in this way throwing it out of focus. The effect of this was that the same improvement in penetration and definition was obtained, but on a much shorter distance. Attention was also called to a method of clamping the object in position when the focus had been obtained; also to a plan for obtaining a fine adjustment by a tangent screw.—Mr. Mills's note on a sponge with stelliform spicules was read.—Mr. Crisp referred to some comments which had recently been made in America upon the advantages of the method of tilting the stage of the microscope as a means of obtaining a very economical and simple fine adjustment, on which some discussion took place.—Dr. A. C. Stokes's paper on new Infusoria Flagellata from American fresh-waters, containing descriptions of twenty new species, was read.—A paper on the Foraminifera of the Red Chalk, by Messrs. H. W. Burrows, C. D. Sherborn, and Rev. G. Bailey, was also read.

PARIS.

Academy of Sciences, June 4.—M. Janssen, President, in the chair.—On the equilibrium of a heterogeneous mass in rotation, by M. H. Poincaré. This is a generalization (worked out on a fresh basis) of M. Hamy's theorem of fluids in rotation. If all the surfaces of the several liquid layers in contact were ellipsoids, then all these ellipsoids would be homofocal, which is impossible unless all the layers be assumed of equal density.—On the rainbow, by M. Mascart. The results are here published of the author's researches on this phenomenon in connection with M. Boitel's recent communication on the supernumerary arcs of the rainbow.—Experimental researches on the action of the brain, by M. Brown-Séquard. The experiments with rabbits here described tend to show that the so-called motor centres and the other parts of one hemisphere of the encephalon may determine movements in both sides of the body through the influence of gravitation alone. This conclusion, while opposed to the generally accepted doctrines, is in harmony with the views advocated by M. Brown-Séquard in previous communications to the Academy. It is evident, he remarks, that the motor zone of each side of the brain is capable of producing movements in the corresponding members on either side, and not, as is commonly supposed, on that side alone which is opposed to the centre of irritation.—Observations of Sawerthal's comet made at the Observatory of La Plata with the Gautier 0·217m. equatorial, by MM. Beuf, MacCarthy, Salas, and Delgado. These observations cover the period from March 9 to April 2, 1888, and the position of the Observatory is given at lat. $-34^\circ 54' 30''\cdot 3$, long. W. of Paris 4h. 0m. 58s.—Determination of the ohm by M. Lippmann's electrodynamic method, by M. H. Wuilleumier. The true value of the ohm as worked out by this process is given by the relation $\frac{106 R'}{R}$, the resistance of the conductor between two given points A and B being $R = 0\cdot 301889 . 10^9$. The value thus obtained is represented by the resistance at 0° of a column of mercury with section 1mmq. and length 106·27cm.—On electro-chemical radiophony, by MM. G. Chaperon and E. Mercadier. By the method here adopted, the authors have succeeded in obtaining an electro-chemical radiophone whose effects are analogous to those of the selenium electric instruments, possessing equal intensity and being capable of like applications.—On the action of the alkaline phosphates on the alkaline earthy oxides, by M. L. Ouvrard. The author has made a comparative study of baryta, lime, and strontian, for the purpose of determining the nature of the compound substances that may be obtained by fusion of these bases and some of their salts with the alkaline phosphates.—On some new gaseous hydrates, by M. Villard. To those already known the author now adds analogous hydrates of methane, ethane, ethylene, acetylene, and protoxide of nitrogen. They are generally less soluble, less easily liquefied, than those previously obtained, and are decomposed at the respective temperatures of 21°·5, 12°, 18°·5, 14°, and 12°. It is shown in the case of methane and ethylene that a gas may form a hydrate above its critical temperature of liquefaction, and that these two gases have a critical temperature of decomposition considerably higher than the others.—Contribution to the study of the ptomaines, by M. Oechsner de Coninck. Having recently obtained a ptomaine in $C_8H_{11}N$, the author here determines by analysis a certain number of salts, and describes the preparation of the chloromercurates and iodomethylate.—On the development of the grain of wheat, by M. Balland. It results from these studies that wheat may be advantageously reaped eight or ten days earlier than is customary. During this latter period the grain ceases its independent growth, and may continue to complete its development just as well in the cut ear as on the standing stalk. The point is obviously of great importance to growers, who have thus so much more time to harvest their crops.—Influence of the organic temperature on convulsions produced by cocaïne, by MM. P. Langlois and Ch. Richet. Some experiments are described tending to show that the higher the temperature of the animal the more susceptible it becomes to the toxic effects of cocaïne. It is inferred that refrigeration should be a general method apt to diminish the effects of toxic substances causing convulsions.—On the chemical action and vegetative alterations of animal protoplasm, by M. A. P. Fokker. Continuing his already-described experiments, the author here shows that, besides the property of producing fermentations, protoplasm possesses that of undergoing vegetative changes, thus confirming his already expressed opinion that the formation of hematocytes is a case of heterogenesis.

STOCKHOLM.

Royal Academy of Sciences, June 6.—A review of the researches on the electricity of the air, by Prof. Edlund.—Researches on the elasticity and tenacity of metallic wires, by Dr. Isberg.—On the probability of finding large numbers in the development of irrational decimal fractions and of continued fractions, by Prof. Gyldén.—Researches on a non-linear differential equation of the second order, by the same.—On the forms and varieties of the common herring, by Prof. F. A. Smitt.—On the integration of the differential equations in the N body, problem iv., by Prof. Dillner.—New remarks on the genus Williamsonia, by Prof. A. G. Nathorst.—Contributions to the knowledge of the hydroids of the western coast of Sweden, by M. Segerstedt.

THURSDAY, JUNE 21, 1888.

THE STEAM-ENGINE.

The Steam-Engine. By G. C. V. Holmes. (London: Longmans, 1887.)

THIS treatise is intended as an elementary text-book for technical students. In many respects it fulfils its purpose, at least better than any book of moderate size with which we are acquainted. It is clearly written; its arrangement, if not the best possible, is orderly; it is so far practical that problems arising in the actual design and use of steam-engines are not ignored, but attacked in a sufficiently elementary way; and the *rationale* of processes involved in the use of steam is explained adequately and correctly on the whole. The woodcuts represent fairly good examples of construction, with the exception of one or two, like those of the injector and exhaust-ejector, which are antiquated, and one or two others so bad that they are obviously mere imaginary sketches. Nevertheless the book fails of being what a really good elementary text-book of the steam-engine might easily be—what, indeed, anyone of Mr. Holmes's competence would make it, if some experience in teaching had shown him the needs and difficulties of engineering students. It is a little to be feared that Mr. Holmes's book is marred by an attempt in part to adapt it to the requirements of some existing examinations on the steam-engine, which are more scrappy and less scientific than the worst of existing text-books. If only a really adequate practical and elementary text-book were written, it would control the examinations instead of needing to be adapted to them.

The treatise includes the mechanics, the thermodynamics, and rules for the design of steam-engines. The portions included under the last head are by far the weakest portions of the book. The scattered discussions of the strength of some portions of engines and boilers are too vague and general to be of practical value. The rules for the strength of fly-wheels at p. 246, and that for area of steam passages at p. 204, are examples of the kind of useless rules which stop short of encountering any one of the actual difficulties of ordinary designing. It is just these portions of the book which seem designed to meet the exigencies of a student cramming for an examination, and the book would be improved by their omission. An elementary treatise on the steam-engine might well leave questions of design on one side, and confine itself to a descriptive account of engines and boilers, with theory enough to explain the actions involved. But then it is neither necessary nor useful in such a treatise to introduce elementary physics and mechanics. A technical student may be assumed to know elementary science. "I have not assumed," says the author, "the slightest acquaintance on the part of the reader with the sciences of heat and motion, and have consequently devoted many pages to the explanation of such parts of these sciences as are necessary for the proper understanding of the working of engines." Hence we find a chapter on the nature of heat, including a discussion of the melting of ice, and the graduation of thermometers. There are definitions of mass, weight, force, and velocity, and arithmetical examples of the laws of motion. Surely all this would only be justifiable in an age when elementary books were scarce and dear. An ordinary student finds it a tiresome obstruction, when the way to the subject of the book is barred by such repetition. On the other hand, a brief but clear and critical account of the methods by which Regnault determined the fundamental constants for steam would have been very useful. It would have shown both the meaning of the terms used, and the probable trustworthiness of the determinations. In place of this, we find only verbal definitions and formulæ.

The thermodynamical portion of the book is probably its best and clearest part, and that in which it is most in advance of any quite elementary book of a similar kind. It must be understood that in criticizing this portion we do not ignore the fact that the author has done a service to elementary technical students.

On p. 67 a diagram is copied from Maxwell, and called a diagram of isothermals of dry saturated steam. It has escaped the author that for dry saturated steam there is no isothermal. At a point in the curve, say at 212°, the steam is saturated: on one side of this it is a mixture of steam and water, or conventionally wet steam; on the other side it is superheated steam. The saturation curve so useful in steam-engine calculations is nowhere mentioned. Further, in any modern treatment of the steam-engine it ought to be recognized that the engineer is always or almost always dealing not with dry saturated steam but with wet steam. The algebraical expressions for the total heat, &c., of wet steam should be introduced along with those for dry steam. Curiously, nowhere in this book can we find an expression for the latent heat of steam, though no quantity is so often required. The total heat is given, and so the latent heat can be inferred, but surely the ordinary approximate expression for latent heat is also useful.

In Chapter III. the theory of perfect engines is given. Following the precedent of treatises of wider scope, the author begins with the laws of expansion of permanent gases. Next the theorem about a reversible engine is given, but in a form in which it is restricted to the case of an air-engine. The efficiency of the reversible engine so obtained is afterwards spoken of as the efficiency of perfect heat-engines in general. But the independence of the result on the nature of the fluid employed is nowhere indicated. The diagram for a perfect steam-engine is given on p. 113. But no elementary student will perceive why the efficiency of this is the same as that of the air-engine, at least without explanation. The only idea ordinary students get from the theorem about the Carnot engine is that the efficiency of *any* engine is proportional to the range of temperature in the cylinder. In the case of the actual steam-engine this is so wrong as to be nearly the reverse of the truth, and the misconception is hardly anywhere adequately guarded against. It is very doubtful whether the Carnot engine ought to be introduced into the elementary theory of the steam-engine. An ordinary indicator-diagram can be taken, and the relation of the heat expended to the heat utilized determined. From the feed measurement and indicator-diagram the steam liquefied at the end of admission and at exhaust can be ascertained. The heat expenditure corresponding to work of admission, expansion, and expulsion can be calculated. From the condenser measurement the heat abandoned can be found, and an estimate formed of the loss by radiation. Repeating the calculation for different degrees of expansion, and perhaps for cases of a jacketed and unjacketed cylinder, really clear notions will be formed of the relative importance of the processes going on in the engine. All this can be done in a perfectly elementary way, and the student will soon perceive that it is in the direct study of the losses of heat, and not in attempts to realize the conditions of a Carnot engine, that improvement is to be sought.

We fail to see the use of reviving the antiquated empirical treatment of Navier and de Pambour given in Chapter IV. De Pambour's equations involve so many assumed quantities that they are practically useless. The author might have remembered that contrary to de Pambour's view the friction of an engine is not proportional to the load, but very nearly independent of it.

Chapter V. deals with the mechanics of the engine. But the simplest graphic methods for finding curves of crank pin effort and acceleration are not given. The next chapter, on slide-valve diagrams, is one of the clearest and most useful in the book.

In Chapter XI. the very difficult question of cylinder condensation is treated on the whole clearly and with insight. But the obscurities of this difficult part of the explanation of the steam-engine are, as might be expected, not quite removed. The author probably attaches much too great importance to radiation from the cylinder sides to the steam, and too little to conduction from the cylinder sides to the water lying on its surface. The following passage will certainly puzzle a student :—

"The second cause—excess of condensation over re-evaporation—is a most fruitful source of waste, and should be most carefully guarded against. It results in the continuous accumulation of water in the cylinder, and consequently causes an amount of waste which goes on increasing with each stroke."

Of course, if the accumulation is continuous the cylinder must get full, which is impossible. In steady working, initial condensation must exactly equal re-evaporation and water carried mechanically to the condenser. Priming and condensation during expansion may for the argument be neglected. What is prejudicial is not excess of condensation over re-evaporation, but retention of water in the cylinder after exhaust.

THE ANIMAL ALKALOIDS.

On the Animal Alkaloids, the Ptomaïnes, Leucomaïnes, and Extractives in their Pathological Relations. By Sir William Aitken, Knt., M.D., F.R.S., Professor of Pathology in the Army Medical School. (London: H. K. Lewis, 1887.)

A Treatise on the Animal Alkaloids, Cadaveric and Vital; or, The Ptomaïnes and Leucomaïnes chemically, physiologically, and pathologically considered in Relation to Scientific Medicine. By A. M. Brown, M.D. With an Introduction by Prof. Armand Gautier, of the Faculté de Médecine of Paris, &c. (London: Baillière, Tindall, and Cox, 1887.)

THE advancement of modern chemistry has increased our knowledge of the alkaloids occurring in the vegetable kingdom—bodies which are of great importance both in a therapeutical and a toxicological aspect. Since the year 1872, a new mode of natural origin of alkaloids has been discovered, viz. from animal sources, and the knowledge and investigation of these bodies have proved of great service in the study of both physiological and pathological chemical processes.

Ptomaïnes were first discovered in decomposing animal tissues, as their pseudonym of "cadaveric alkaloids" implies. Their presence in these dead tissues introduced a new factor in the *post-mortem* search for poisons in suspected cases—a factor, however, the importance of which has been somewhat exaggerated. A more important result of their discovery has been the explanation of the cases of poisoning by decayed animal foods, such as sausages, tinned and putrid meats, in which they have been found.

Further researches have, moreover, brought to light the fact that similar bodies of an alkaloidal nature may be produced within, and by, the living organism. In this case they may be considered as of "vital" origin, the products, that is, of the metabolism of protoplasm; or they may, in some cases, be the result of the decomposition of albuminoid bodies: in both cases, the term "leucomaïnes" has been used to designate them. A leucomaïne—peptotoxin—has, for example, been found by Brieger as a product of artificial peptic digestion; another has been discovered in the body of the sea-mussel (*Mytilus edulis*), and to its presence were ascribed the symptoms of poisoning which occurred in Wilhelmshaven, in many people who had eaten the shell-fish. These facts, of the origin of poisonous alkaloids by the decomposition of albuminoid bodies, and also in the living animal tissues, open out a wide field of research in pathology, and have perhaps led to more speculation than our present knowledge warrants.

The two books before us deal with the whole subject of poisonous alkaloids. Sir W. Aitken's small work owes its origin to an introductory lecture delivered by him at the Army Medical School at Netley. It is chiefly a short *résumé* of the work done on the subject. The second part of the *brochure* will be found of interest to medical men, as it gives the direction in which modern thought is tending with regard to the part played by poisonous alkaloids in the production of disease. The conclusions drawn can, in the present state of our knowledge, be considered merely as suggestions: many more facts must come to light before the *rôle* played by the "vital" alkaloids in pathological processes can be adequately, or even reasonably, discussed.

Dr. Brown's work is of a more ambitious nature, and purports to be a treatise on the subject of animal alkaloids generally. After commencing with a short history of the subject, the author proceeds to give an account of the methods for extraction of the alkaloids, and of the chemical and physiological properties of ptomaïnes; the "vital" alkaloids, leucomaïnes, being treated in a similar manner. The account of the methods of extraction might, we think, be made more practical by being considered a little more fully, as it is to this part of the book that workers in this field will turn for information.

Of the chemical and physiological properties of these alkaloids, a fairly complete account is given: our knowledge of these properties is, however, up to the present so imperfect, that the researches carried on during the last sixteen years only serve as a basis for future work. Much has yet to be done regarding the physiological action of these bodies; and no progress can be made in this respect until the alkaloids have been extracted in a pure state. It is almost useless, in the interests of science, to speak of the action of alkaloids extracted by various reagents; though, in certain cases of poisoning, the investigation of such an action may be of immediate utility. Dr. Brown has devoted much space to the consideration of the part played by the vital alkaloids in physiological or pathological conditions. In his account he has closely followed the views of M. Gautier, whose researches have thrown great light on the subject.

Dr. Brown's work may be recommended as giving a general account of the present state of our knowledge regarding these alkaloids. S. H. C. M.

PRACTICAL FORESTRY.

Practical Forestry: its Bearing on the Improvement of Estates. By Charles E. Curtis, F.S.T., F.S.S., Professor of Forestry, Surveying, and General Estate Management at the College of Agriculture, &c. (London: *Land Agent's Record* Office, 1888.)

THE present work is described as a reprint of a series of papers on "Practical Forestry," which appeared in the *Land Agent's Record*, and the author's object in republishing his ideas on practical forestry is to promote and encourage the study of true forestry among the British land-owners and land agents, and especially to impress upon students the necessity of acquiring a sound practical knowledge of a branch of land economy so long neglected and ignored. So far so good; but when the author says, "I trust this publication will be the means of spreading this object more widely" (*sic*), we fear that he will be grievously disappointed.

To begin with: the book is written in doubtful English. Though the correct use of the English language is not absolutely essential, yet in order to be a really useful work, a book should be written in language which complies with the ordinary grammatical rules, and which is also intelligible to the class of readers expected to profit by its perusal. The whole book is conceived in a very narrow spirit, and the expressed views of the author are frequently open to question. Take for instance the following passage (p. 40):—

"The great and true principle of thinning is to encourage the growth of those trees which are left, and not to secure a financial present return. This, though important, is quite a secondary consideration, and should at all times be ignored."

We beg to say that the great and true principle of thinning is nothing of the kind. In every instance the owner, or his manager, must consider what the objects of his management are. They may be:—

(1) To produce material of a certain description.

(2) To produce the greatest possible number of cubic feet per acre and year.

(3) To secure the highest possible money return from the property.

(4) To secure the highest possible interest on the invested capital.

(5) To improve the landscape, or to affect the climate, &c.

In each of these cases the method of thinning will be different.

Again, the description given of a true forester (p. 12) is somewhat illusory. If the author thinks that a man who has studied botany, vegetable physiology, geology, entomology, &c., is also able to wield the axe, and use with skill the pruning saw or knife, he is likely to be disappointed in nine cases out of ten. Such ideas are theoretical speculations, and not the result of practical experience.

The chapter on "Soil and Site" is of a very hazy description whenever the author attempts to rise above ordinary platitudes. He promises to describe clearly in future sections the nature of the soils and sites in which the individual trees most delight, but, as far as we can see, he has got over the difficulty by omitting to redeem his promise.

To sum up, the book is not likely to further the object which the author seems to have at heart. The experienced forester will find nothing new in it, and the beginner will only meet with badly arranged statements which are frequently not in accordance with the teaching of science or of practice. Sw.

OUR BOOK SHELF.

Tropical Africa. By Henry Drummond. (London: Hodder and Stoughton, 1888.)

THIS is a brightly-written and most interesting sketch of Mr. Drummond's experiences during a recent journey in East Central Africa. He has no very surprising or exciting adventures to describe, but in the course of his narrative, which is written with a vigour and grace unusual in books of travel, he contrives to convey a remarkably vivid impression of the country through which he passed. Going up the valley of the Shiré River, he visited Lake Shirwa, of which little has hitherto been known; then he went on to Lake Nyassa, and to the plateau between Lake Nyassa and Lake Tanganyika. During the whole of his journey he was a close observer, not only of the physical features of the districts he visited, but of the various classes of phenomena which interested him as a geologist, an ethnographer, and a student of natural history. In one admirable chapter he gives a full and striking account of the white ant, which he had frequent opportunities of studying; in another he brings together many curious illustrations of the well-known fact that among numerous species of animals mimicry is one of the means of self-protection. Before going to Africa, Mr. Drummond had mentally resolved not to be taken in by "mimetic frauds," yet he was "completely stultified and beaten" by the first mimetic form he met. This was an insect—one of the family of the *Phasmidæ*—exactly like a wisp of hay. Another insect, which he often saw, closely resembles a bird-dropping, and the consequence is that "it lies fearlessly exposed on the bare stones, during the brightest hours of the tropical day, a time when almost every other animal is skulking out of sight." Mr. Drummond has of course much to say about the chances of a great future for Africa, and in this connection he presents a good deal of valuable information as to the capacity of the natives for work and as to the wrongs inflicted upon them by vile gangs of slave-traders.

Plotting, or Graphic Mathematics. By R. Wormell, D.Sc., M.A. (London: Waterlow and Sons, Limited, 1888.)

THIS book is intended chiefly for those who have mastered the beginnings of algebra and Euclid, and so is very elementary. The method employed throughout is that of using squares, and preparatory exercises are first given to show the student the different purposes to which they may be applied with facility. Proportion and the determination of areas are the subjects of the first two chapters, followed by a chapter on the tracing of paths of projectiles, with various data. The sections of the cone, such as the parabola, ellipse, and hyperbola, are next described, with various methods of tracing them. The book contains a great number of numerical examples, and concludes with a chapter on the higher graphs and curves of observation.

The Elements of Logarithms. By W. Gallatly, M.A. (London: F. Hodgson, 1888.)

IN this little book of thirty-one pages the various rules and methods of treating logarithms are stated and explained in a simple and precise way, and those beginning the subject would do well to read through these few pages. Numerous examples are put in here and there, and at the end the author has added a collection of questions taken from the Woolwich and Sandhurst examination papers for the years 1880-87.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Thunderstorms and Lightning Accidents.

As the season of thunderstorms and lightning accidents is now approaching, I hope you will kindly allow me to make known through your columns the fact that, in the interests of science, the Institute of Medical Electricity is very desirous of obtaining authentic information concerning lightning accidents, whether fatal or otherwise. I should therefore esteem it a favour if some of the many friends of humanity among your readers will assist us to investigate these phenomena by sending me such particulars of accidents of this nature as they may have personal or trustworthy knowledge of as soon after they occur as possible.

Of course, electrical and physiological details are what we most require, but trustworthy general information is often valuable, and will be gratefully received.

24 Regent Street, S.W. H. NEWMAN LAWRENCE.

Nose-Blackening as Preventive of Snow-Blindness.

I ONLY read Prof. Ray Lankester's letter the other day on the above, which appeared in NATURE of May 3 (p. 7). I have made inquiries among travellers in the snow regions of North America, and find the practice to be quite common and well known, but have met with no one who can explain it. I may say, however, that when I visited New Zealand in 1884 there were in one of the canoes which came off to our ship several naked natives, who had disfigured their faces by blackening their noses and eyes, and running a black fillet round the face, which gave them a villainous aspect; and I, in that insolent ignorance which seems to prevail with all pious people who have dealings with "the heathen of the isles," believed they had got themselves up in this way in order to frighten us. But it may well have been for other reasons. Certainly the sun's heat, reflected from the still waters of the sea, was quite as painful as any I ever felt in the regions of the silver snow. I subsequently found that the black used by these people, who are of a pale complexion, was the oxide of manganese, called in their tongue *labán*.

A. J. DUFFIELD.

The Delaware, Keweenaw Michigan, U.S.A., June 4.

The *Lethrus cephalotes*.

THE beetle which is described in your issue of June 7 (p. 134), by the British Consul at Varna, is probably the *Lethrus cephalotes*, which has proved so destructive to vineyards in East and South-East Europe. It is a dull black beetle, easily recognized by the swollen truncated ends of the antennæ; its length is about 21 mm. It lives chiefly in dry and sandy soil, and during dry weather the beetles leave their holes generally between nine and eleven in the morning and after three in the afternoon, to attack the tender parts of the vine, as Mr. Brophy describes.

Taschenberg is of the opinion that the buds, &c., of the vine which are dragged back to the holes of the beetles serve as food for the larvæ. As the beetles show a marked aversion to water, it is possible that the pest might be lessened by copiously watering the infected areas. ARTHUR E. SHIPLEY.

Christ's College, Cambridge, June 16.

Proposed Fuel-testing Station for London.

WILL you allow me to put before your readers the following proposition for the establishment of such a station, the desirability of which has been much impressed upon me within the last few years? So far as I know, there does not exist anything of the kind in this country where, as on the Continent, coals can be tested for their evaporative power, the gases of combustion analyzed, and all the results carefully reported on by experts. I subjoin a few details of the proposed station, with probable cost. It should, I consider, be placed on a perfectly independent footing, and managed by experts, under a small committee appointed by those who assist with money or otherwise. It might follow generally the lines of existing coal-testing stations, but with all modern improvements.

In this country it is remarkable that neither the sellers of coal take the trouble to find out how much heat they are offering, nor the purchasers how much they are getting for their money, and this notwithstanding the hundreds of millions of tons of coal changing hands yearly. Colliery-owners and coal-merchants, as well as the large consumers, know very little about coal calorimeters, although the former sell so much heat, and the latter try to utilize it to the best advantage. How few of the latter weigh their coal regularly, or keep any weekly record of the quantities of ashes and clinkers, to find out how much dirt and incombustible matter they are paying for! How few know what it costs them in fuel to evaporate one thousand gallons of water into steam, which is one of the best standards of comparison in a given district!

Locality.—The station might be in close proximity to a river, canal, or railway-station, so that the coals could be delivered easily and cheaply, and the steam allowed to escape under pressure without causing annoyance. A small piece of land doubtless could be obtained in such a situation at a low rent. The boiler-shed should be about 35 × 20 feet, with a small additional shed for storing the fuel.

Cost.—It would be desirable to allow at least £700 for a start, to cover the cost of the boiler-shed, chimney, 20 horse-power boiler (if such were considered large enough), and the special arrangements for measuring the feed-water with tanks, scales, feed-pump, injector, gas and coal analyzing apparatus, calorimeters, &c. Seeing that until the objects of the station become known it would probably not pay expenses, the help of guarantors would no doubt be necessary.

Yearly Expenses.—The charge for testing and reporting upon each combustible would probably more than cover eventually the salaries of a technical manager, his assistant, and the stoker. Some arrangement might possibly be made by which the manager and his assistant should only attend when required, at any rate at first, in order to diminish expenses.

The station would require to be advertised and made known in various ways. Colliery-owners would no doubt find it to their advantage to have their different kinds of coal tested and reported upon, so as to offer them to their customers with their ascertained heating value or evaporative power. Large consumers of coal (railway companies, water-works, and others) should know the heating value of the coal they are paying for, and the percentage of incombustibles.

I add a few notes on the temporary and permanent experimental heat stations known to me.

(1) The earliest fuel-testing station was established in 1847 at Brix, in Germany.

(2) Sir H. de la Beche and Dr. Lyon Playfair made a series of

experiments before the year 1851 with different coals suitable for the Navy. These trials were conducted near London, under a small marine boiler at atmospheric pressure.

(3) At the English Government dockyards, various interesting experiments have been made under small marine boilers, and the results published in Blue-books.

(4) Messrs. Armstrong, Longridge, and Richardson published in 1858 an account of some valuable experiments they had made with the steam-coals of the Hartley district of Northumberland, under a small marine boiler, for the Local Steam Colliery Association.

(5) At Wigan many excellent experiments were made by Messrs. Richardson and Fletcher about 1867, to test the value of Lancashire and Cheshire steam-coals for use in marine boilers. The water was evaporated under atmospheric pressure from a small marine boiler. This station was afterwards abolished.

In none of the above do the gases of combustion appear to have been analyzed.

(6) A fuel-testing station was worked at Dantzig in 1863.

(7) An important station was opened at Brieg, on the Oder, by the colliery-owners of Lower Silesia in April 1878, with the primary object of testing the value as fuel of the important coal-seams of that province. After working with the most satisfactory results for two years, and establishing the superiority of the Lower Silesian coal, the experiments terminated in 1880. The testing boilers had each 40 square metres of heating surface. Gases and coals were analyzed.

Existing Continental Stations.—(8) The Imperial Naval Administration Coal-testing Station at Wilhelmshaven, Germany, was established in 1877.

(9) Dr. Bunte's coal-testing station, erected at Munich about 1878, particulars of which have been published in the Proceedings of the Institution of Civil Engineers, vol. lxxiii. Here some hundreds of trials have been reported on and published; much valuable work has been done, and many fuels tested, including coals of the Ruhr valley, Saar basin, Saxon and Bohemian coal-fields, and those of Silesia and Upper Bavaria. The boiler of the station has about 450 square feet of heating surface. The gases and coals are analyzed, and all particulars carefully noted. It is one of the most complete stations I have seen.

(10) In Belgium, near Brussels, there is a Government station for testing fuels, under the administration of the Belgium State railways; locomotive boilers are used. The establishment has been at work for the last two years, but no results are published, as they are considered the property of the Government. Private firms can, however, have their coals tested and reported upon.

(11) The Imperial Marine Station, Dantzig.

(12) Boiler Insurance Company at Magdeburg.

The above is a slight outline of the work already done in this direction.

With the view of obtaining the opinions of those interested in starting a fuel-testing station, I ask you kindly to give this letter publicity. If the necessary sum can be raised, we may hope to have before long a practical and useful establishment in London, and to gain from it many interesting practical results respecting the combustion of fuels. BRYAN DONKIN, JUN.

Bermondsey, S.E., June 11.

The Geometric Interpretation of Monge's Differential Equation to all Conics—the Sought Found.

THE question of the true geometric interpretation of the Mongian equation has been often considered by mathematicians. In the first place, we have the late Dr. Boole's statement that "here our powers of geometrical interpretation fail, and results such as this can scarcely be otherwise useful than as a registry of integrable forms" ("Diff. Equ.," pp. 19-20). We have next two attempts to interpret the equation geometrically. The first of these propositions, by Lieut-Colonel Cunningham, is that "the eccentricity of the osculating conic of a given conic is constant all round the latter" (*Quarterly Journal*, vol. xiv. 229); the second, by Prof. Sylvester, is that "the differential equation of a conic is satisfied at the sextactic points of any curve" (*Amer. Journ. Math.*, vol. ix. p. 19). I have elsewhere considered both these interpretations in detail, and I have pointed out that both of them are irrelevant; the first of them is, in fact, the geometric interpretation, not of the Mongian equation, but of one of its five first integrals which I have actually calculated (Proc. Asiatic Soc. Bengal, 1888, pp. 74-86); the second is out of mark as failing to furnish such a property of the conic as would lead to a geometrical quantity which vanishes at every point of every conic (Journal Asiatic Soc. Bengal, 1887, Part 2, p. 143). In this note I will briefly mention the true geometric interpretation which I have recently discovered.

Consider the osculating conic at any point, P, of a given curve; the centre, O, of the conic is the centre of aberrancy at P, and as P travels along the given curve, the locus of O will be another curve, which we may conveniently call the *aberrancy curve*. Take rectangular axes through any origin; let (x, y) be the given point P, and α, β the co-ordinates of the centre of aberrancy. Then it can be shown without much difficulty that

$$\alpha = x - \frac{3qr}{3qs - 5r^2},$$

$$\beta = y - \frac{3q(pr - 3q^2)}{3qs - 5r^2},$$

whence

$$\frac{d\alpha}{dx} = \lambda \mathrm{T}, \quad \frac{d\beta}{dx} = \mu \mathrm{T},$$

where

$$\lambda = \frac{r}{(3qs - 5r^2)^2}, \quad \mu = \frac{pr - 3q^2}{(3qs - 5r^2)^2},$$

$$\mathrm{T} \equiv 9q^2t - 45qrs + 40r^3,$$

p, q, r, s, t being, as usual, the successive differential coefficients of y with respect to x.

If $d\psi$ be the angle between two consecutive axes of aberrancy, ds the element of arc, and ρ the radius of curvature of the aberrancy curve, we have

$$\rho = \frac{ds}{d\psi}, \quad ds^2 = d\alpha^2 + d\beta^2,$$

whence

$$\rho = (\lambda^2 + \mu^2)^{\frac{1}{2}} \cdot \mathrm{T} \cdot \frac{dx}{d\psi}.$$

But it is easy to show that

$$\frac{d\psi}{dx} = \frac{q(3qs - 5r^2)}{r^2 + (rp - 3q^2)^2},$$

so that

$$\rho = \mathrm{T} \cdot \frac{\{r^2 + (rp - 3q^2)^2\}^{\frac{3}{2}}}{q(3qs - 5r^2)^3}.$$

Now, $\mathrm{T} = 0$ is Monge's differential equation to all conics, and when $\mathrm{T} = 0$ we have $\rho = 0$. Hence, clearly, the true geometric interpretation of the Mongian equation is:

The radius of curvature of the aberrancy curve vanishes at every point of every conic.[1]

This geometrical interpretation will be found to satisfy all the tests which every true geometrical interpretation ought to satisfy, and I believe that this is the interpretation which, during the last thirty years, has been sought for by mathematicians, ever since Dr. Boole wrote his now famous lines. I will not take up the valuable space of these columns with the details of calculation: they will be found fully set forth in two of my papers which will be read next month before the Asiatic Society of Bengal, and will in due course be published in the Journal.

Calcutta, May 18. ASUTOSH MUKHOPADHYAY.

PERSONAL IDENTIFICATION AND DESCRIPTION.[2]

I.

IT is strange that we should not have acquired more power of describing form and personal features than we actually possess. For my own part I have

[1] The differential equation of all parabolas,

$$3qs - 5r^2 = 0,$$

is also easily interpreted, viz. calling the distance OP between the given point and the centre of aberrancy the *radius of aberrancy*, and the reciprocal of this (= I) the *index of aberrancy*, we have, easily,

$$\mathrm{I} = \frac{3qs - 5r^2}{3q\{r^2 + (rp - 3q^2)^2\}^{\frac{1}{2}}},$$

so that the interpretation is that *the index of aberrancy vanishes at every point of every parabola.*

[2] The substance of a Lecture given by Francis Galton, F.R.S., at the Royal Institution on Friday evening, May 25, 1888.

frequently chafed under the sense of inability to verbally explain hereditary resemblances and types of features, and to describe irregular outlines of many different kinds, which I will not now particularize. At last I tried to relieve myself as far as might be from this embarrasment, and took considerable trouble, and made many experiments. The net result is that while there appear to be many ways of approximately effecting what is wanted, it is difficult as yet to select the best of them with enough assurance to justify a plunge into a rather serious undertaking. According to the French proverb, the better has thus far proved an enemy to the passably good, so I cannot go much into detail at present, but will chiefly dwell on general principles.

Measure of Resemblance.—We recognize different degrees of likeness and unlikeness, though I am not aware that attempts have been as yet made to measure them. This can be done if we take for our unit the *least discernible difference*. The application of this principle to irregular contours is particularly easy. Fig. 1 shows two such contours, A and B, which might be meteorological, geographical, or anything else. They are drawn with firm lines, but of different strengths for the sake of distinction. They contain the same area, and are so superimposed as to lie as fairly one over the other as may be. Now draw a broken contour which we will call C, equally subdividing the intervals between A and B; then C will be more like A than B was. Again draw a dotted contour, D, equally subdividing the intervals between C and A; the likeness of D to A will be again closer. Continue to act on the same

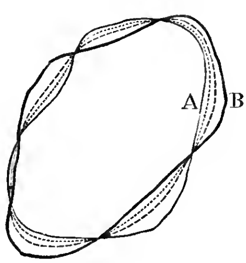

Fig. 1.

principle until a stage is reached when the contour last drawn is undistinguishable from A. Suppose it to be the fourth stage; then as $2^4 = 16$, there are 16 grades of least-discernible differences between A and B. If one of the contours differs greatly in a single or few respects from the other, reservation may be made of those peculiarities. Thus, if A has a deep notch in its lower right-hand border, we might either state that fact, and say that in other respects it differed from B by only 16 grades of unlikeness, or we might make no reservation, and continue subdividing until all trace of the notch was smoothed away. It is purely a matter of convenience which course should be adopted in any given case. The measurement of resemblance by units of least-discernible differences is applicable to shades, colours, sounds, tastes, and to sense-indications generally. There is no such thing as infinite unlikeness. A point as perceived by the sense of sight is not a mathematical point. but an object so small that its shape ceases to be discernible. Mathematically, it requires an infinitude of points to make a short line; sensibly, it requires a finite and not a large number of what the vision reckons as points, to do so. If from thirty to forty points were dotted in a row across the disk of the moon, they would appear to the naked eyes of most persons as a continous line.

Description within Specified Limits.—It is impossible to verbally define an irregular contour with such precision that a drawing made from the description shall be undistinguishable from the original, but we may be content with a lower achievement. Much would be gained if we could refer to a standard collection of contours drawn with double lines, and say that the contour in question falls between the double lines of the contour catalogued as number so-and-so. This would at least tell us that none of the very many contours that fell outside the specified limits could be the one to which the description applied. It is an approximate and a negative method of identification. Suppose the contour to be a profile, and for simplicity's sake let us suppose it to be only the portion of a profile that lies below the notch that separates the brow from the nose and above the parting between the lips, and such as is afforded by a shadow sharply cast upon the wall by a single source of light, such as is excellently seen when a person stands side-ways between the electric lantern and the screen in a lecture-room. All human profiles of this kind, when they have been reduced to a uniform vertical

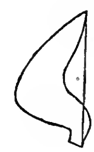

Fig. 2.

scale, fall within a small space. I have taken those given by Lavater, which are in many cases of extreme shapes, and have added others of English faces, and find that they all fall within the space shown in Fig. 2. The outer and inner limits of the space are of course not the profiles of any real faces, but the limits of many profiles, some of which are exceptional at one point and others at another. We can classify the great majority of profiles so that the whole of each class shall be included between the double borders of one, two, or some small number of standard portraits such as Fig. 3. I am as yet unprepared to say how near together the double borders of such standard portraits should be; in other words, what is the smallest number of grades of unlikeness that we can satisfactorily deal with. The process of sorting profiles into their proper classes and of gradually

Fig. 3.

building up a well-selected standard collection, is a laborious undertaking if attempted by any obvious way, but I believe it can be effected with comparative ease on the basis of measurements, as will be explained later on, and by an apparatus that will be described.

Classification of Sets of Measures.—Prisoners are now identified in France by the measures of their heads and limbs, the set of measures of each suspected person being compared with the sets that severally refer to each of many thousands of convicts. This idea, and the practical application of it, is due to M. Alphonse Bertillon. The actual method by which this is done is not all that could be theoretically desired, but it is said to be effective in action, and enables the authorities quickly to assure themselves whether the suspected person is or is not an old malefactor. The primary measures in the classification are four—

namely, the head length, head breadth, foot length, and middle-finger length of the left foot and hand respectively. Each of these is classified according as it is large, medium, or small. There are thus three, and only three, divisions of head lengths, each of which is subdivided into three divisions of head breadth; again, each of these is further subdivided into three of foot length, and these again into three of middle-finger length; thus the number of primary classes is equal to three multiplied into itself four times—that is to say, their number is eighty-one, and a separate pigeon-hole is assigned to each. All the exact measures and other notes on each criminal are written on the same card, and this card is stored in its appropriate pigeon-hole. The contents of each pigeon-hole are themselves sub-sorted on the same principle of three-fold classification in respect to other measures. This process can, of course, be extended indefinitely, but how far it admits of being carried on advantageously is another question. The fault of all hard-and-fast lines of classification, when variability is continuous, is the doubt where to find values that are near the limits between two adjacent classes. Let us take the case of stature, for

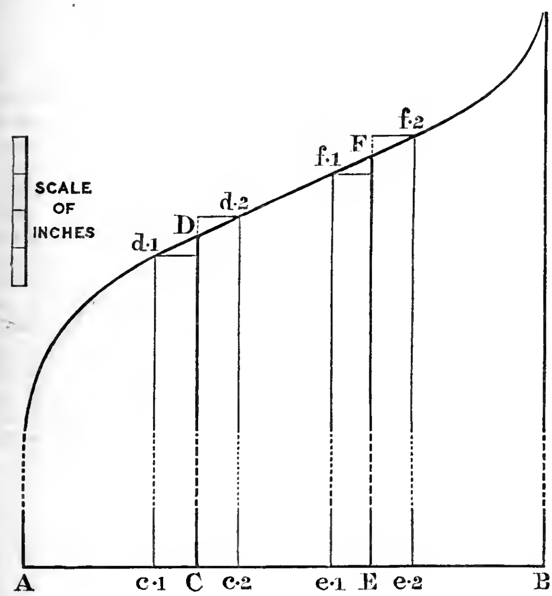

Fig. 4.

illustration of what must occur in every case, representing its distribution by what I have called a "scheme," as shown in Fig. 4.

Here the statures of any large group of persons are represented by lines of proportionate length. The lines are arranged side by side at equal distances apart on a base, A B, of convenient length. A curve drawn through their tops gives the upper boundary of the scheme; the lines themselves are then wiped out, having served their purpose. If the base A B be divided into three equal parts, and perpendiculars, C D, E F, be erected at the divisions between them, reaching from the base up to the curve, then the lengths of those perpendiculars are proportionate to the limiting values between the small and the medium group, and the medium and the large group, respectively. The difference between these perpendiculars in the case of stature is about 2·3 inches. In other words, the shortest and tallest men in the medium class differ only by that amount. We have next to consider how much ought reasonably to be allowed for error of measurement. Considering that a man differs in height by a full third of an inch between the time of getting up in the morning and lying down at night; considering also that measures are recorded to the nearest tenth of an inch at the closest, also the many uncertainties connected with the measurement of stature, it would be rash not to allow for a possible error of at least ± half an inch. Prolong C D, and note the points upon it at the distance of half an inch above and below D; draw horizontal lines from those points to meet the curve at $d.1$, $d.2$, and from the points of intersection drop perpendiculars reaching the base at $c.1$, $c.2$. A similar figure is drawn at F. Then the ratio borne by the uncertain entries to the whole number of entries is as $c_1c_2 + e_1e_2$ to AB. This, as seen by the diagram, is a very serious proportion. There is a dilemma which those who adopt hard and-fast lines of classification cannot avoid: either the fringe of uncertainty is dangerously wide, or else the delicacy with which measures are made is not turned to anything like its full account. If the delicacy is small, the fringe of uncertainty must be very wide; if the delicacy is great, the fringe will be narrow; but then the other advantages of possessing delicate observations are wasted through employing only a few classes. The bodily measurements are so dependent on one another that we cannot afford to neglect small distinctions. Thus long feet and long middle-fingers usually go together. We therefore want to know whether the long feet in some particular person are accompanied by particularly long, or moderately long, or relatively short fingers, though the fingers may in the two last cases be long as compared with those of the general population, and will be treated as long in M. Bertillon's system of classes. Certainly his eighty-one combinations are far from being equally probable. The more numerous the measures the greater would be their interdependence, and the more unequal would be the distribution of cases among the various possible combinations of large, small, and medium values. No attempt has yet been made to estimate the degree of their interdependence. I am therefore having the above measurements (with slight necessary variation) recorded at my anthropometric laboratory for the purpose of doing so. This laboraiory, I may add, is now open to public use under reasonable restrictions. It is entered from the Science Collections in the Western Galleries at South Kensington.

Mechanical Selector.—Feeling the advantage of possessing a method of classification that did not proceed upon hard-and-fast lines, I contrived an apparatus that is quite independent of them, and which I call a mechanical selector. Its object is to find which set out of a standard collection of many sets of measures, resembles any one given set within specified degrees of unlikeness. No one measure in any of the sets selected by the instrument can differ from the corresponding measure in the given set, by more than a specified value. The apparatus is very simple, it applies to sets of measures of every description, and ought to act on a large scale with great rapidity, and as well as it does on a small one, testing several hundred sets by each movement. It relieves the eye and brain from the intolerable strain of tediously comparing a set of many measures with each successive set of a large series, in doing which a mental allowance has to be made for a *plus* or *minus* deviation of a specified amount in every entry. It is not my business to look after prisoners, and I do not fully know what need may really exist for new methods of quickly identifying suspected persons. If there be any real need, I should think that this apparatus, which is contrived for other purposes, might, after obvious modifications, supply it.

The apparatus consists of a large number of strips of card or metal, *c1*, *c2* (Fig. 5), say 8 or 9 inches long, and having a common axis, A, passing through all their smaller ends. A tilting-frame, T, which turns on the same axis, has a front cross-bar, F, on which the tips of the larger ends of all the cards rest whenever the machine is left alone. In this condition a counterpoise at the other end of T suffices to overcome the weight of all the cards, and this heavy end of T lies on the base-board S. When the heavy end of T is lifted, as in Fig. 5, its front-bar is of course depressed, and the cards being individually acted on by their own weights are free to descend with the cross-bar unless they are otherwise prevented. The lower edge of each card is variously notched to indicate the measures of the person it represents. Only four notches are shown in the figure, but six could easily be employed in a card of eight or nine inches long, allowing compartments of 1 inch in length, to each of six different measures. The position of the notch in the compartment allotted to it, indicates the corresponding measure according to a suitable scale. When the notch is in the middle of a compartment, it means that the measure is of mediocre amount; when at one end of it, the measure is of some specified large value or of any other value above that; when at the other end, the measure is of some specified small value or of any other value below it. Intermediate positions represent intermediate values according to the scale. Each of the cards corresponds to one of the sets of measures in the standard collection. The set of measures of the given person are indicated by the positions of parallel strings or wires, one for each measure, that are stretched

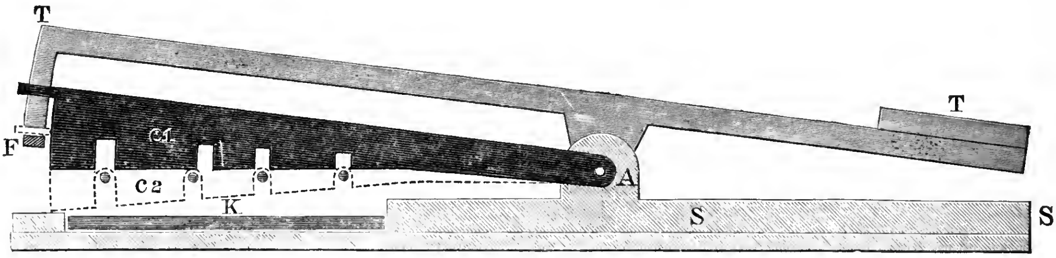

Fig. 5.—Section of the apparatus, but the bridge and rod are not shown, only the section of the wires.

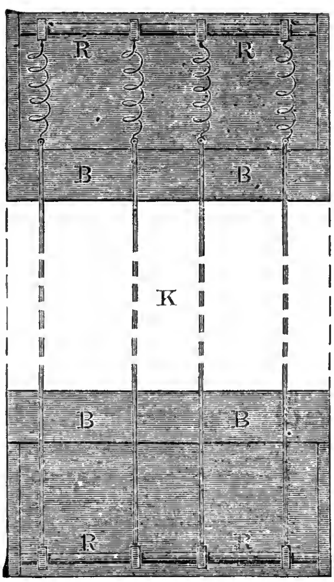

Fig. 6*a*.
Plan and section of the key-board K.

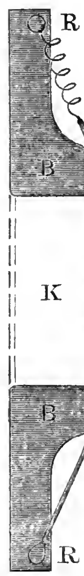

Fig. 6*b*.

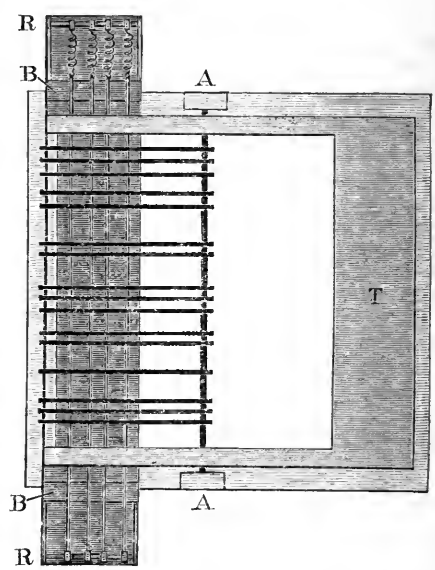

Fig. 7.—Reduced plan of complete apparatus.

Explanation:—A, the common axis; c_1, c_2, the cards; T, tilting-frame, turning on A (the cards rest by their front ends on F, the front cross-bar of T, at the time when the heavy hinder end of T rests on the base-board S); K, key-board, in which R, R are the rods between which the wires stretch; B, B, are the bridges over which the wires pass.

across bridges at either end of a long board set crossways to the cards. Their positions on the bridges are adjusted by the same scale as that by which the notches were cut in the cards. Figs. 6*a* and 6*b* are views of this portion of the apparatus, which acts as a key, and is of about 30 inches in effective length. The whole is shown in working position in Fig. 7. When the key is slid into its place, and the heavy end of the tilting-frame T is raised, all the cards are free to descend so far as the tilting-frame is concerned, but they are checked by one or more of the wires from descending below a particular level, except those few, if any, whose notches correspond throughout to the positions of the underlying wires. This is the case with the card c_2, drawn with a dotted outline, but not with c_1, which rests upon the third wire, counting from the axis. As the wires have to sustain the weight of all or nearly all the cards, frequent narrow bridges must be interposed between the main bridges to sustain the wires from point to point. The cards should be divided into batches by partitions corresponding to these interposed bridges, else they may press sideways with enough friction to interfere with their free independent action. Neither these interposed bridges nor the partitions are drawn in the figure. The method of adjusting the wires there shown is simply by sliding the rings to which they are attached at either end, along the rod which passes through them. It is easy to arrange a more delicate method of effecting this if desired. Hitherto I have snipped out the notches in the cards with a cutter made on the same principle as that used by railway guards in marking the tickets of travellers. The width of the notch is greater than the width of the wire by an amount proportionate to the allowance intended to be made for error of measurement, and also for that due to mechanical misfit. There is room for 500 cards or metal strips to be arranged in sufficiently loose order within the width of 30 inches, and a key of that effective length would test all these by a single movement. It could also be applied in quick succession to any number of other collections of 500 in each.

Measurement of Profiles.—The sharp outline of a photograph in profile admits of more easy and precise measurement than the yielding outline of the face itself. The measurable differences between the profiles of different persons are small, but they are much more numerous than might have been expected, and they are more independent of one another than those of the limbs. I suspect that measures of the profile may be nearly as trustworthy as those of the limbs for approximate identification—that is, for excluding a very large proportion of persons from the possibility of being mistaken for the one whose measurements are given. The measurement of a profile enables us to use a mechanical selector for finding those in a large standard collection to which they nearly correspond. From the selection thus made the eye could easily make a further selection of those that suited best in other respects. A mechanical selector also enables us to quickly build up a standard collection step by step, by telling us whether or no each fresh set of measures falls within the limits of any of those already collected. If it does, we know that it is already provided for; if not, a new card must be added to the collection. There will be no fear of duplications, as every freshly-added standard will differ from all its predecessors by more than the specified range of permitted differences. After numerous trials of different methods for comparing portraits successively by the eye, I have found none so handy and generally efficient as a double-image prism, which I largely used in my earlier attempts in making composite portraits. As regards the most convenient measurements to be applied to a profile for use with the selector, I am unable as yet to speak decidedly. If we are dealing merely with a black silhouette, such as the shadow cast on a wall by a small or brilliant light, the best line from which to measure seems to be B C in Fig. 8; namely, that which touches both the concavity of the notch between the brow and nose, and the convexity of the chin. I have taken a considerable number of measures from the line that touches the brow and chin, but am now inclined to prefer the former line. A sharp unit of measurement is given by the distance between the above line and another drawn parallel to it just touching the nose, as at N in the figure. A small uncertainty in the direction of B C has but a very trifling effect on this distance. By dividing the interval between these parallel lines into four parts, and drawing a line through the third of the divisions, parallel to B C, we obtain the two important points of reference, M and R. M is a particularly well-defined point, from which O is determined by dropping a perpendicular from M upon B C. O seems the best of all points from which to measure. It is excellently placed for defining the shape and position of the notch between the nose and the upper lip, which is perhaps the most distinctive feature in the profile. O L can be determined with some precision; O B and O C are but coarse measurements. In addition to these and other obvious measures, such as one or more to define the projection of the lips, it would be well to measure the radius of the circle of curvature of the depression at B, also of that between the nose and the lip, for they are both very variable and very distinctive. So is the general slope of the base of the nose. The difficulty lies not in selecting a few measures that will go far towards negatively identifying a face, but in selecting the best—namely, those that can be most precisely determined, are most independent of each other, most variable, and most expressive of the general form of the profile. I have tried many different sets, and found all to be more or less efficient, but have not yet decided to my own satisfaction which to adopt.

A closer definition of a profile or other curve, can be based upon the standard to which it is referred. Short cross-lines may be drawn at critical positions between the two outlines of the standard, and be each divided into eight equal parts. The intersection of the cross-lines with the outer border would always count as 0, that with the inner border as 8, and the intermediate divisions would count from 1 to 7. As the cross-lines are very short, a single numeral would thus define the position of a point in any one of them, with perhaps as much precision as the naked eye could utilize. By employing as

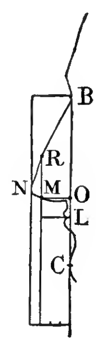

FIG. 8.

many figures as there are cross-lines in the standard, each successive figure for each successive cross-line, a corresponding number of points in the profile would be accurately fixed. Suppose a total of nine figures to be given, together with a standard collection of under a thousand doubly outlined portraits, each with six cross-lines. The first three figures would specify the catalogue number of the portrait to be referred to, and the remaining six figures would determine with much accuracy, six points in the outline of the portrait that it is desired to describe.

I have not succeeded in contriving an instrument that shall directly compare a given profile with those in a standard collection, and which shall at the same time act with anything like the simplicity of the above, and with the same quick decision in acceptance or rejection. Still, I recognize some waste of opportunity in not utilizing the power of varying the depths of the notches in the cards, independently of their longitudinal position.

I shall have next to speak of other data that may serve for personal identification, and especially on the marks left by blackened finger-tips upon paper.

(*To be continued.*)

SOAP-BUBBLES.

SOAP-BUBBLES fill the same happy position as do those charming books in which Lewis Carroll describes the adventures of Alice, in that they serve equally to delight the young and to attract the old. Clerk-Maxwell has mentioned the fact that on an Etruscan vase in the Louvre are seen the figures of children amusing themselves with bubbles, while to-day the same subject is being forced on the attention of the world by a strange development of modern enterprise. On the other hand, the bubble has occupied the minds of scientific men of all times. Sir Isaac Newton, Sir David Brewster, and Faraday, not to mention many others, devoted themselves to the soap-bubble as a means for investigating the subtleties of light. Plateau a few years ago delighted men of science with that wonderful book in which he, a blind man, expounded, in the clearest and most elegant manner, the result of years of labour on this one subject. Lately, Profs. Reinold and Rücker have employed the soap-film in investigations which tend to throw more light on the molecular constitution of bodies. These experiments will be remembered by all who saw them as being no less beautiful than instructive. The latest experiments with bubbles, which were shown by Mr. C. V. Boys to the Physical Society and at the Royal Society *conversazione*, and of which a full account is to be found in the May number of the *Philosophical Magazine*, depend upon no property which is not well known, and, unlike those referred to above, are not intended to increase our scientific knowledge; and yet no one would have ventured to predict that bubbles would submit to the treatment described in the paper, or would have expected such simple means to produce such beautiful results.

The first property of the soap-film turned to account is that strange reluctance of two bubbles to touch one another. Just as a bubble may be danced on the sleeve of a serge coat, or even embraced, without wetting the sleeve or being broken, so can two bubbles be pressed together until they are materially deformed without really touching one another at all. One bubble may be blown inside another, and if the heavy drops which accumulate at the bottom are removed, the inner one may be detached and rolled about within the outer one; or the outer one, held by two moistened rings of wire (Fig. 1),

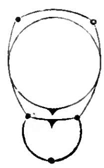

Fig. 1.

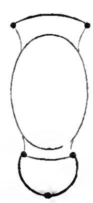

Fig. 2.

may be pulled out so as to squeeze the inner one into an oval form (Fig. 2), or may even be swung round and round, and yet the inner one remains free and independent, and when the outer is broken it floats gently away. If the inner one is coloured with the fluorescent material uranine, it shines with a green light, while the outer one remains clear as at first, showing that there is no mixture and no contact.

When the inner bubble is blown with coal gas, it rests against the upper side of the outer one (Fig. 3), pulling it

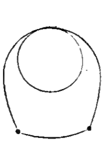

Fig. 3.

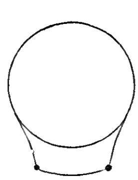

Fig. 4.

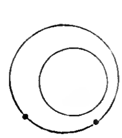

Fig. 5.

more and more out of shape as its size increases (Fig. 4). It can even be made to tear the outer one off the ring to which it was attached, after which the two bubbles rise in the air one inside the other. The outer bubble may be held by a light ring of thin wire to which thread and paper are attached, and then when an inner bubble of coal gas is blown, it will carry up the outer bubble, ring, paper, and all; and yet, in spite of this weight pressing them together, the inner bubble refuses to touch the outer one. If a little gas is let into the outer of two bubbles, the inner one will remain suspended like Mahomet's coffin (Fig. 5).

Diffusion of gas through a soap-film is shown by lowering a bell-jar of coal-gas over a bubble in which a second one is floating (Fig. 6). By degrees the gas penetrates the outer bubble, until the inner one, insufficiently buoyed up, gently sinks down.

The heavy and inflammable vapour of ether is made use of to show the rapidity with which the vapour of a liquid which will mix with the soap solution will penetrate through the walls of a bubble. A large

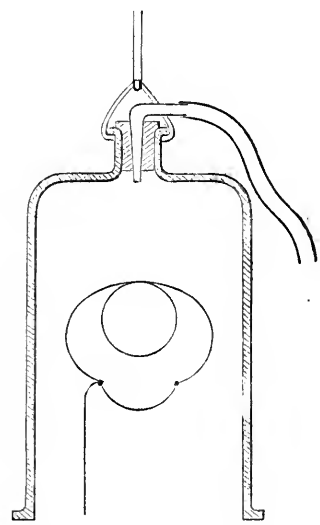

Fig. 6.

Fig. 7.

inverted bell-jar has some ether poured into it, after which bubbles blown with air in the usual way may be dropped into the jar, when they will float upon the vapour. They are then taken out and carried to a flame, when a blaze of light shows that the inflammable vapour has penetrated through the film. A bubble blown at the end of a wide tube and lowered into the vapour hangs like a heavy drop when removed; and if held in the beam of an electric light the vapour is seen oozing through the film and falling away in a heavy stream, while a light applied to the

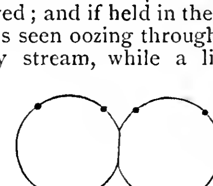

Fig. 8.

mouth of the tube fires the issuing inflammable vapour, and a large flame like that of a bunsen burner is the result (Fig. 7).

A variety of experiments are described in which bubbles are rolled along troughs made of soap-film—either straight, circular, or spiral—the prominent feature being that bubbles will roll upon or within one another as if they were made of india-rubber; they will even, where apparently in contact, take up the vibrations of a tuning-fork, and this will not force them to touch. There is one influence, however, which they cannot resist, and that is electrification. When two bubbles which are resting against one another (Fig. 8), provided that one is not within the other, are exposed to the influence of an even feebly electrified body, they instantly coalesce and become one (Fig. 9), and so act as a delicate electroscope. When one bubble is within the other, the outer one may be pulled out of shape by electrical action, and yet the inner one is perfectly screened from the electrical influence, thus showing in a striking manner that there is no electrical force within a conductor not even as near the surface as one side of a soap-film is near the other; for though the force outside is so great that the bubble is deformed, yet the fact that the inner one remains separate shows that the force within is too small to be detected. One of the experiments described shows at the same time the difference between the behaviour of two bubbles, one blown inside a third, and the other brought to rest against the third from the outside. Under these conditions, if electricity is produced

FIG. 9.

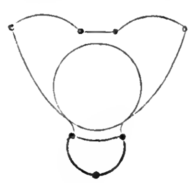

FIG. 10.

in the neighbourhood, the two outer bubbles become one, and the inner one, unharmed, rolls down and rests at the bottom of the now enlarged outer bubble (Fig. 10).

One experiment is described in which a cylindrical bubble is blown with oxygen gas between the poles of an electro-magnet. If the length is properly adjusted, the bubble breaks into two directly the exciting current is turned on, though the force due to the magnetic nature of oxygen is so feeble that not the slightest change of shape can be detected in a spherical bubble under the same conditions.

For other experiments and for details, readers are referred to the original paper in the *Philosophical Magazine*, the editor of which has kindly allowed us to reproduce the illustrations used in this article.

THE PARIS OBSERVATORY.

THE Annual Report of the Paris Observatory, which has recently appeared, draws special attention to the two events which have rendered the past year memorable, not merely in the history of the Observatory, but in that of astronomical science as a whole. The first of these was, of course, the meeting at Paris of the International Congress for the execution of the photographic chart of the heavens, and Admiral Mouchez gives the names of the members of the Congress, and the resolutions adopted by them. Of the Permanent Committee appointed by the Congress, Admiral Mouchez is himself the President, and he has already issued the first number of the *Bulletin de la Carte du Ciel*, future numbers of which will be brought out by the Committee as occasion may require. Twelve Observatories, including that of Paris, had definitely pledged themselves to join in the scheme, and five or six more expected to be able to do so shortly, so that there should be no difficulty in completing the chart within three or four years. The International Exhibition to be held at Paris next year would furnish a good opportunity for the reassembling of the Permanent Committee in order that the final decisions relating to the carrying out of this great scheme might be formed.

The other great event was the publication of the first two volumes of the great Paris Catalogue, the revision of the Catalogue of Lalande. This last work, which has already been referred to in NATURE (vol. xxxvii. p. 569), was commenced in 1855, but owing to many unfavourable circumstances has only been pushed forward vigorously during the last ten years, and now is all but completed. As the stars which still require observation have become fewer and more scattered, it has been found no longer necessary to devote more than one instrument to the work; the great meridian instrument has therefore been set apart for this work, and for the observation of minor planets and comparison stars, whilst the other meridian instruments have been left free for the careful study of the places of fundamental stars and for special researches. The "garden" circle has accordingly been used for the observation of circumpolars after M. Lœwy's plan, and the Gambey mural circle by M. Perigaud for the redetermination of the latitude of the Observatory. The value found for this latter by a series of *consecutive* observations of Polaris at upper and lower transit is 48° 50′ 12″·0, but Admiral Mouchez considers that despite the care and skill of M. Perigaud this determination falls short of the desired accuracy on account of the uncertainty of the corrections for refraction. This is partly due to the observations having all been made during midsummer, but chiefly to the bad position of the Observatory at the extreme south of Paris, the observations of Polaris therefore being made with the telescope pointed over the entire breadth of the city. It is hoped that the great Eiffel tower may render assistance to the study of refraction by affording much information as to inversions of the usual law of the variation of temperature with the height. The above value for the latitude still remains to be corrected for flexure of the instrument, and M. Perigaud is now undertaking the study of this error. The total number of meridian observations obtained during the year was 16,318, the highest monthly number having been secured in February, a most unusual circumstance. The observations of sun, moon, and planets amounted to 545.

The observations with the equatorials have been of the usual kind. M. Bigourdan has made 400 measures of nebulæ with that of the West Tower; and M. Obrecht, with the equatorial *coudé*, has made 720 measures of lunar craters referred to different points of the limb, in order to secure a better determination of the form of our satellite. But a yet more important work with this latter instrument has been the thorough examination of its theory by MM. Lœwy and Puiseux. In view of the success of the Paris telescope, of the number of similar instruments now under construction, and of the still wider popularity which the same form will probably have in the future, this was a work much to be desired.

The results, however, achieved in the field of astronomical photography are those in which, in view of the proposed chart, the greatest interest will be felt just now, and here the MM. Henry have further evidences of progress to present. Saturn and the moon have been photographed with a direct enlargement of 20 diameters. The phases of the lunar eclipse of August 3 have been recorded by the same means. With the smaller photographic instrument, aperture 4·3 inches, negatives have been obtained, one of which showed more than 30,000 stars on the single plate. Several curious new nebulæ have been discovered, one 1° in length near ζ Orionis; but the most remarkable have been those in the Pleiades. Two plates of this group, each with an exposure of four hours, have not only added much to our knowledge of the nebulæ round Electra, Merope, Maia, and Alcyone, these no longer appearing as mere faint clouds, but as well-marked nebulosities of intricate and complicated forms, but two new nebulæ are shown, both very narrow and straight, the longer one being some 40′ in length and but 2″ or 3″ in breadth, and threading together as it were no fewer than seven stars. The plate representing this photograph of the Pleiades, which is attached to the Report, shows 2326 stars, and comprises stars of the 18th magnitude, instead of the 1421 stars contained in the earlier photograph. MM. Henry have been likewise engaged in the study of the new instrument they have devised for the measurement of the stellar photographs, and in the preparation of tables of instrumental corrections, and of corrections for the effect of refraction; whilst M. Thiele has been inquiring into the degree of accuracy of which the measures are capable, with most encouraging results, and Admiral Mouchez considers that the precision thus attainable "will permit the carrying out under good conditions of the Catalogue of all the stars down to the 11th magnitude as decided by the Congress." It should be noted, however, that this interpretation of the resolution of the Congress has been challenged, and it has been urged that the Catalogue to be formed was to contain simply as many suitably placed stars as would be necessary as reference points for the great photographic chart, and that stars down to the 11th magnitude might be used for this purpose.

As to the publications of the Observatory, the first volume of the Catalogue, 0h.–6h. of R.A., is shortly to be followed by the second, 6h.–12h., the first sheets of which were already in the printers' hands. The volume of Observations for 1882 was published last August, that for 1883 was passing through the press, whilst the reduction of apparent to mean places was completely finished for 1884. The nineteenth volume of the Memoirs was in course of publication, and would contain, besides the works mentioned in the Report for 1886, a memoir on the theory of the figure of the planets, by M. Callandreau, and another on an allied subject, by M. Hamy. Amongst the works published by the individual members of the Observatory, the most important have been M. Lœwy's new method for the determination of the constant of aberration, and a work by M. Wolf, on the pendulum. M. Leveau is still engaged in his work upon Vesta, and M. Bossert is preparing for the determination of a definitive orbit of the Pons-Brooks comet. Under the head of "Matériel" the progress of the new equatorial *coudé* of 2 feet aperture and 60 feet focal length is referred to. Its completion is expected during the present year, but the building for it has not yet been begun.

The chief exception to the record of progress which Admiral Mouchez's Report supplies is found in the short paragraph which records the closing of the astronomical school, on financial grounds. The necessity for this step is to be most deeply regretted.

THE PHOTOGRAPHIC CHART OF THE HEAVENS.

WE lately reprinted from the *Observatory* (NATURE, May 10, p. 38) an article by the editors of that periodical on Dr. Gill's proposal that two million stars should be catalogued. The following is the reply of the editors, printed in the June number of the *Observatory*, to letters addressed to them on the subject by Admiral Mouchez and Mr. E. B. Knobel:—

We print above letters from Admiral Mouchez and from Mr. Knobel, concerning the remarks we made last month on Dr. Gill's proposition to catalogue 2,000,000 stars. There is a somewhat personal implication in both letters, to which we must at once reply before proceeding to treat of the real question at issue—a suggestion that we have been so emphatic in our disapproval of the scheme as to be discourteous to its supporters. We may perhaps venture to doubt whether either writer has done us the honour to read our remarks carefully enough. Admiral Mouchez "nous trouve bien sévère pour un projet aussi bien étudié et venant d'un savant aussi habile et compétent que le Directeur de l'Observatoire du Cap." We have not said a single word in disparagement of the skill and care with which Dr. Gill's paper has been written; we have vehemently objected to the question being raised at all; and that we have objected so vehemently may be taken as a full recognition of Dr. Gill's prominent position, which makes it a matter of necessity to bring all our forces to bear against a scheme which he chooses to advance. Mr. Knobel is perhaps more unjust to us. We have not in an unqualified manner characterized a catalogue of 2,000,000 stars as "an utter waste of time, labour, and money"; but we did use even stronger language about cataloguing stars "for the purpose only of getting their places written down," in order to call attention to the *reductio ad absurdum* of cataloguing towards which we very much fear there is some apparent tendency. And, finally, if we have been so emphatic as to be accused of exaggeration, let us again point out that a scheme, which we contend has not been assented to or even considered by the members of the Astrophotographic Conference, has been quietly launched, and is now so far under way that it is referred to by the President in the opening sentence of his letter as a matter already accepted by the "Comité permanent," and as only remaining to be discussed in detail. Surely it is time for those who have the welfare of the scheme really sanctioned by the Conference to raise their voices loudly in protest!

So much in explanation of the tone we have adopted in speaking of this proposal, and we now return to the letters. The main point of both is that this scheme of a catalogue of 2,000,000 stars has not been originated by Dr. Gill, but was really considered and approved by the Conference. As we have stated above, we hold the opposite opinion,—that although two resolutions of the Conference do mention *a* catalogue, this term cannot be supposed to sanction a catalogue of 2,000,000 stars without further specification. The Conference met to discuss the advisability of making a chart. With the invitations sent out to the various astronomers to attend this Conference there was sent a "programme provisoire" (which, it is to be very much regretted, was not that considered by the Congress). This first "programme provisoire" was dropped, and at the first *séance* of the Congress another was produced. In the first, in article 19 a *catalogue of reference stars* was mentioned, and properly so, but in the second there was no mention of any such catalogue. Mention was made in section 4 of a means of publishing the chart and the form of publication, but up to this time there was absolutely no question before the Conference of publication of a catalogue either of 2,000,000 or any other number of stars. There was no doubt a feeling amongst some astronomers present that a catalogue would be as useful, in their judgment, as the chart; and they took the opportunity of putting forward their views when the question of a second series of plates was brought forward. The taking of this second series of plates was proposed to meet an anticipated difficulty in photographing parts of the heavens where the stars differed greatly in magnitude. It was decided (Resolution 17) that a second series of plates should be taken, in order to insure the greatest precision in the micrometrical measurement of the stars of reference, and to render possible the construction of a catalogue. Here we have the first mention of a catalogue in the resolutions noted. A reference to the minutes of the Congress will show that this resolution was a compromise, for there had already been before the Congress a direct proposition (that of M. Tacchini) for a catalogue, which, however, was not voted upon. The resolution was in fact an endeavour to settle a question that was before the Congress, viz. whether the plates should be so taken as to be capable of accurate measurement; and this is decided by the specification that they shall render possible the construction of a catalogue. The next two resolutions speak of the second series of plates as *destinés à la construction du catalogue*, but nowhere is any direct resolution to be found as to the construction of a catalogue of all the stars.

If these resolutions need interpretation by the light of subsequent consideration at all, we may suggest a very different direction in which they might be modified in actual fact, and in which their spirit would yet be even better represented than by a literal fulfilment. It was pointed out that in taking the photographic plates of stars down to the 14th magnitude in parts of the sky where brighter stars existed, these with the exposure necessary to obtain the 14th magnitude would be very much over-exposed. And it was suggested that it would be advisable to take a second series of plates, as already mentioned (see Resolution 17). Now in some parts of the sky no second series of plates are, from this point of view, at all necessary; whilst in others not one or two, but many series of plates would be necessary in order to do justice to the various magnitudes in that particular part of the sky. For the present this is not the point at issue, but it may serve as an illustration of the sort of interpretation of the resolutions which we should consider legitimate.

In order to come to a proper judgment on the legitimacy of the derivation of Dr. Gill's proposal from the resolutions it is necessary to make some statements, which are not new, but of which the true significance does not seem to have been universally appreciated:—(1) When the plates are obtained they are actual representations of the stars as existing at a given time, and for every purpose except spectrum analysis are as good, if not better, than the visible heavens. If with these plates we have the absolute places of a certain small number of known stars, we have then all the data to make them valuable, either in the present or in the future. (2) The many questions concerning the stars which it is hoped a photographic chart of the heavens would do a great deal towards settling, such as their distribution, their proper motions, their changes of magnitude, and the presence of minor planets, of new stars and the like, can all be best treated by a direct comparison of plate with plate, in any of the various ways in which this can be done. (3) In order to obtain the best results from such an agent as photography it is necessary to use it in its own proper way; and astronomers must recollect that old methods of procedure adapted to other instrumental means may most probably be out of place. We might considerably enlarge on these statements, but for our present purpose it is sufficient to call attention to them.

Now, if Dr. Gill's catalogue were successfully constructed—and there are, alas! many difficulties in the way—its utility in the direction of comparison of our sky with that of the future is wholly limited by one condition, that in the future another exactly similar catalogue be constructed, occupying a similar time. Even then, if any changes were found by means of this comparison of catalogues which might very well be made in the course of fifty or one hundred years, the natural and indeed the proper thing to do would be to immediately compare the original plates. But can it be possible that any man or number of men really think of dealing with such a subject in such a way? If, on the other hand, the object of a catalogue be merely to allow of comets, minor planets, and other bodies being located, surely it would be better to measure the plates as occasion arises, and not to catalogue 2,000,000 stars on the off-chance of having some twenty or thirty positions to settle in the course of a year. And, further, such a catalogue would have this enormous disadvantage, that whilst in some parts of the sky stars of the 11th magnitude would be fairly well spread, in the Milky Way we should have stars clustered in such enormous quantities that it would be an extremely difficult thing to even identify them: in fact, speaking roundly, we should say that if such a catalogue were made, two-thirds of the stars catalogued would lie in the Milky Way. If, contrary to the opinion we have expressed, it is decided to form a very large catalogue, surely it would be better to determine the places of a certain number of stars, of such magnitudes as are found available, in each square degree, and make these the reference stars from which the positions of the other stars on the plate could be obtained.

We are therefore of opinion that, supposing limitless time and money available for such a purpose, the advantages of constructing this catalogue would be doubtful; but even if we waived all these objections and agreed that such a catalogue would be a "nice thing to have," or admitted that since men of the ability and reputation of Admiral Mouchez and Dr. Gill consider such a catalogue necessary it is heresy to inquire the why and wherefore, there would still be left the serious objection that to form a chart of the heavens is the first thing to do, and, take it in as simple a form as possible, it will quite possibly tax the energies of astronomers to their utmost; and that stellar photography being as yet in its infancy it is suicidal to attempt anything which will commit us to a course of action extending over more than a very few years. We could not give a better illustration of the dangers of the opposite procedure than has been supplied by Admiral Mouchez himself. In a recent article he has suggested that there have lately been such improvements in the sensitiveness of plates that we could now go to the 15th magnitude instead of the 14th. With a little ingenuity and less arithmetic it could easily be shown that the whole plan of operations would have become hopelessly futile and obsolete before half the time allowed by Dr. Gill for its completion had elapsed.

But not for one moment do we wish to appear lacking in sympathy with those who have spent and are spending so much time and thought on this subject; it is our great anxiety for the success of the work in which they are co-operating which makes us eager to protest as far as we can against the grand mistake of attempting too much.

THE INCURVATURE OF THE WINDS IN TROPICAL CYCLONES.

THE question of the incurvature of the winds in tropical cyclones is one of such importance to mariners, to enable them to judge their position in a storm, and to escape the hurricane around the central calm, that no apology is needed for adding my independent testimony to that of Prof. Loomis, whose conclusions, given at length in his recent well-known memoir, "Contributions to Meteorology," are quoted in Mr. Douglas Archibald's paper on M. Faye's work "Sur les Tempêtes" in last week's NATURE (p. 149).

In the preparation of a forthcoming work on the weather and climates of India and the storms of Indian seas, I have lately had occasion to re-investigate the above question in the case of cyclones in the Bay of Bengal, on the evidence afforded by the numerous original memoirs and reports prepared by Messrs. Willson, Eliot, Pedler, and other officers of the Indian and Bengal Meteorological Departments; my object being the practical one of determining directly the bearing of the storm-centre from a ship's position; and instead, therefore, of measuring the angle between the wind direction and the nearest isobar, as was done by Prof. Loomis, I have measured with a protractor the angle included between the former and its radius vector, in all cases in which the position of the storm's centre has been ascertained on sufficient evidence. In one other important condition I have also departed from the method pursued by Prof. Loomis. I have restricted the measurements to wind observations of ships at sea, within the influence of the storm, and to those of good observatories on the coast, subject to the same proviso; and have taken no account of those of inland observatories. This difference of procedure is probably the reason that the amount of the incurvature shown by these measurements is somewhat different from that obtained by Prof. Loomis, though the general fact of a great incurvature is thoroughly confirmed. My results are as follow:—

(1) The mean of 132 observations between lats. 15° and 22°, within 500 miles of the storm-centre, gives the angle 122° between the wind direction and its radius vector.

(2) The mean of 12 observations between the same latitudes, within 50 miles of the storm-centre, gives the angle 123°.

(3) The mean of 68 observations between N. lats. 8° and 15°, within 500 miles of the storm-centre, gives the angle 129°.

The observations within 50 miles of the storm-centre in the south of the Bay are too few to afford any trustworthy result.

For seamen's guidance, the following practical rules may be formulated:—

(1) In the north of the Bay of Bengal, standing with the back to the wind, the centre of the cyclone bears about five points on the left hand, or three points before the beam.

(2) In the south of the Bay, it bears about four points on the left hand, or four points before the beam.

(3) These rules hold good for all positions *within the influence of the storm*, up to 500 miles from the storm-centre. On the north and west the influence of the storm rarely extends to anything like this distance, but it does to the east and south.

Since much of this evidence, afforded by the Bay of Bengal cyclones, has been before the public for many years, it is incomprehensible to me how a man of M. Faye's scientific eminence can still assert that in the tropics "the wind arrows display an almost rigorous circularity." If, as may possibly be the case, he relies on the evidence of Mr. Piddington's memoirs, ignoring all subsequent work, it is only necessary to examine those memoirs to find that his data do not bear out that author's conclusions. In the charts which accompany Mr. Piddington's later memoirs, the wind observations are, as a rule, not shown, but only the ships' courses, and the author's interpretation of the positions and tracks of the storms. But the evidence is always fully given in the text, and it will be found that when the wind arrows are plotted therefrom, and are sufficiently numerous to allow of the position of the storm's centre being determined, which is far from being generally the case, they are reconcilable only with spiral courses, having a considerable incurvature.

I do not propose now to enter on a formal criticism of Mr. Piddington's work, the great merit of which, as that of a pioneer in the field of storm-science, no one more fully recognizes than myself; but so much seems necessary in explanation of the apparent glaring discrepancy between his results and those of modern workers in the same field.

The evidence of the cyclones of the Bay of Bengal, those tropical cyclones to which M. Faye appeals as authoritative on the validity of his views, is, then, conclusive against him. There is a strong influx of the lower atmospheric strata into a tropical cyclone, proving, in the most unquestionable manner, the existence of an ascending current over the vortex This fact is quite independent of any views that may be entertained as to any theory of cyclone origin and movement of translation, but any such theory must harmonize with the fact, and hence I conceive that it is fatal to M. Faye's views. With these, in so far as they are theoretical merely, I have no present concern, but it is obviously a matter of high importance to seamen that they should not be misled as to the facts of the wind's movement in cyclones, and it is because the promulgation of such views as M. Faye's tends to perpetuate an old and now exploded error of fact, that I have to put in my protest against them.

HENRY F. BLANFORD.

Folkestone, June 15.

NOTES.

It should have been stated in our paragraph last week relative to the opening of the Laboratory of the Marine Biological Association at Plymouth that the President, Prof. Huxley, who has given unremitting care to the affairs of the Association during the last three years, would be present if he were not prevented from taking part in any public proceedings by the state of his health. In the absence of the President, one of the Vice-Presidents of the Association, Prof. Flower, will preside. The Honorary Secretary, Prof. Ray Lankester, who founded the Association, and has conducted its affairs to the present issue, will also be present.

MR. J. J. H. TEALL, who now holds a foremost place among the petrographers of this country, has just been appointed to the Geological Survey. We understand that he will be specially charged with the study of the crystalline schists and the problems of regional metamorphism, and that he will be closely associated with the field officers who are mapping these rocks in different parts of Scotland. The Survey is to be heartily congratulated on this appointment. The staff is now remarkably strong, but the problems with which it is confronted are among the most difficult in geology. These problems have never been attacked by such a united force of field geologists and microscopists, who, working together with one common aim, will no doubt raise still higher the scientific reputation of the Survey, increase our knowledge of the history of the most ancient rocks, and throw light on some of the most puzzling questions in geological science.

THE electors to the Mastership of Downing College, Cambridge, have, by a unanimous vote, chosen Dr. Alexander Hill, Fellow of the College, to succeed Prof. Birkbeck. Dr. Hill's claim to the appointment sprang from his success as a teacher and worker in biology. No appointment to a Headship has been made on this ground alone since the revival of natural science at the Universities.

ON the 4th inst., Dr. Maxwell T. Masters was elected a corresponding member of the Institute of France, in the Botanical Section, in place of the late Prof. Asa Gray. Besides Dr. Masters, the following names appeared on the list of presentation: M. Treub, of Batavia; Mr. Triana, of Paris; M. Warming, of Lund; M. Wiesener, of Vienna. Dr. Masters obtained 39 votes; M. Triana, 5; M. Treub, 1.

THE Sorbonne, consulted as to the proposed creation of a Chair for the teaching of Darwinian theories, has not expressed disapproval of the scheme suggested by the Municipal Council of Paris. It has appointed a committee to report on the matter; and it is expected that no serious opposition will be offered to the proposal.

WE are glad to learn that a pension of £50 has been granted to Mrs. Balfour Stewart from the Civil List.

ON May 25, a complimentary dinner was given at the Queen's Hotel, Manchester, to Prof. Schorlemmer, of the Owens College, by his former pupils, to celebrate the occasion of the conferring of LL.D. upon him by the Senate of the Glasgow University, and to offer their congratulations. In the absence of Sir Henry Roscoe, who had been expected to take the chair, Mr. R. S. Dale, one of Prof. Schorlemmer's eldest pupils and friends, presided. Numerous congratulatory telegrams and letters were received by Dr. Schorlemmer, and early in the evening a letter was read from Sir Henry Roscoe, expressing regret that he could not be present, and testifying to his high appreciation of the ability of his old friend and colleague. Among those from whom congratulatory telegrams were received were Dr. Pauli, Director of the firm of Meister, Lucius, and Brüning, in Hoechst; Prof. Bernthsen, of the Badische Anilin und Sodafabrik, in Ludwigshafen; and Prof. Hermann Kopp, of Heidelberg, the historian of chemistry, who spoke of Prof. Schorlemmer's position as one of the principal pioneers of the science of organic chemistry and one of its foremost exponents, both as a teacher and a writer. Prof. Thorpe, F.R.S., proposed the health, long life, and prosperity of Dr. Schorlemmer, and referred to the fact that Glasgow, which had conferred honour on him, had produced such men as Black and Thomson, names familiar to all chemists.

DR. ASA GRAY left Harvard College in trust, to aid in the support of the Gray Herbarium of Harvard University, the copyrights of all his books, upon condition that proper provision should be made for the renewal and extension of these copyrights by new editions, continuations, and supplements, such as might be needed in the study of botany, and as might best enhance and prolong the pecuniary value of the bequest.

PROF. LOVERING has resigned the Chair of Mathematics and Natural Philosophy which he has held at Harvard for fifty years. In accepting his resignation, which takes effect in the autumn, the President and Fellows of the College have expressed warm appreciation of his services. Prof. Lovering has been President of the American Association, and still presides over the American Academy.

PROF. MCNAB, Swiney Lecturer on Geology in connection with the British Museum, wiil begin a course of twelve lectures on the fossil plants of the Palæozoic epoch on Monday next, at the Natural History Museum, Cromwell Road.

LAST night the *conversazione* of the Society of Arts took place at the South Kensington Museum.

A *conversazione* will be given by the Royal College of Surgeons, at the College, on Wednesday, June 27; and by the Royal Geographical Society, at Willis's Rooms, on Friday, June 29.

AN International Horticultural Exhibition is to be held at Cologne from August 4 to September 19.

WE have received from Messrs. West, Newman, and Co., samples of two kinds of botanical drying paper. One of the kinds differs but little from that which they have supplied for many years, which was originally manufactured, purposely for drying plants, by a paper-maker of the name of Bentall, who lived at Halstead in Essex, and contributed, a generation ago, to the distributions of the London Botanical Society. This paper has been largely used for the last thirty years, and combines in a very satisfactory manner the merits of a high degree of absorbence with a reasonable toughness. No doubt, for drying plants, it is the best paper that can be got, but yet, excepting grasses, Cyperaceæ, and mosses, one or more changes are required in the first few days to make satisfactory specimens in a climate like that of England. The new paper is quite without glaze, and seems a little more absorbent than the old "Bentall." The other kind is copied from an American model, a paper not made expressly for botanical use, sent to England by the late Dr. Asa Gray. It is twice as thick as the "Bentall," much more rigid, and very absorbent; a serviceable paper to mix with the lighter kind for home use, but too heavy to carry about in large quantities.

ACCORDING to *La Nature*, an immense terrestrial globe, constructed on the scale of one-millionth, will be shown at the Paris Exhibition of 1889. A place will be set apart for it at the centre of the Champ de Mars. The globe will measure nearly 13 metres in diameter, and will give some idea of real dimensions, since the conception of the meaning of a million is not beyond the powers of the human mind. Visitors to the Exhibition will see for the first time on this globe the place really occupied by certain known spaces, such as those of great towns. Paris, for instance, will barely cover a square centimetre. The globe will turn on its axis, and thus represent the movement of rotation of the earth. The scheme was originated by MM. T. Villard and C. Cotard, and *La Nature* says that it has been placed under the patronage of several eminent French men of science.

WE have received a sample of tobacco grown by Messrs. James Carter and Co., at a farm in Kent, and cured by Messrs. Cope Brothers and Co. It represents one of the first experimental crops brought to maturity, and passed through the various processes of manufacture, in this country, since the time of Charles II. The packet is accompanied by a card, on which we find the somewhat discouraging counsel: "Examine leisurely—use warily—smoke sparingly." Mr. Goschen was asked the other evening in the House of Commons whether he would cause an inquiry by experts into the results attending the experiment made by Messrs. Cope, with the view, if possible, of relaxing the fiscal restrictions upon the culture of tobacco in Great Britain. The Chancellor of the Exchequer cautiously replied that "only experience would show the value to smokers of this tobacco, and no inquiry by experts would be so valuable as that practical test. If any hon. member wished to try it, samples would be placed in the smoking-room. It was impossible to give any form of relaxation in the fiscal regulations which would injure the revenue."

ACCORDING to the *Kavkaz* newspaper, a shock of earthquake was felt at Julfa, in the Armenian province of Erivan, on May 15, about midday. The first shock was followed by a stronger one, which lasted for about three seconds, and seemed to have a direction from east to west.

THE Council of the Italian Meteorological Society held its first annual meeting at Turin on Sunday, April 15, under the presidency of Padre Denza. It was decided to hold the third general assembly of the Society at Venice, in September next, just before or after the Congress of the Alpine Club at Bologna. The establishment by the Society of a new Observatory in the Argentine Republic was notified, and also of four new meteorological stations in Italy. The arrangements being made with respect to the hygienic stations at five large cities were explained, as well as the proposed method of publication of the observations. The President submitted the Report of the Geodynamic Committee, nominated at the meeting at Aquila (NATURE, vol. xxxvi. p. 614), with reference to seismological observations and the protection of buildings. The Report, which is printed in the monthly Bulletin of the Italian Meteorological Society for May, consists of nine articles, and will be distributed to the Prefects and Mayors of districts liable to earthquake-shocks.

THE Hydrographer of the Admiralty has issued notices of the recent establishment of the following storm-signals:—(1) By the Japanese Government, at forty-seven stations on the coasts of Japan. A red ball, or one red light, to indicate that strong winds are probable from any direction. A red cone, or three red lights in the shape of a triangle, to indicate that strong winds are probable, at first from the northward or southward, according as the apex is upwards or downwards. (2) By the harbour authorities at Chittagong, relative to the signals at that port. A ball, or three lights placed vertically, to indicate that a severe cyclone is near Akyab, and will probably advance towards Chittagong. A drum, or two lights placed vertically, to indicate the early approach of a severe cyclone, with its attendant storm-wave. We take this opportunity of suggesting the desirability of introducing more uniformity in these signals in different countries, wherever practicable.

THE atomic weight of the element osmium has been re-determined by Prof. Seubert. The necessity for this re-determination has been felt ever since the principle of periodicity began to take firm root in the minds of chemists; and the more recent values arrived at for the atomic weights of iridium, platinum, and gold have tended to render this necessity even more imperative. The natural sequence, according to their chemical and physical properties, of the metals of the platinum group is generally accepted as—osmium, iridium, platinum, gold. Now the atomic weight of iridium as determined in 1878 by Seubert is 192·5, that of platinum as fixed by the same chemist in 1881 is 194·3, and that of gold as estimated last year by Thorpe and Laurie, and by Krüss, is 196·7, while the recognized atomic weight of osmium as given by Berzelius in 1828 is so high as 198·6. Obviously, if the grand conception of Newlands, Mendelejeff, and Lothar Meyer is correct, the atomic value of osmium required most careful revision. Such an undertaking, however, is endowed with peculiar interest owing to the dangerous nature of work with the osmium compounds, and many chemists who have been interested in this subject have been deterred by the knowledge that accidental contact with the fumes of the tetroxide, which are so frequently evolved by the spontaneous decomposition of many osmium compounds, might deprive them of the use of their eyes for ever. Prof. Seubert has happily succeeded without accident in establishing the validity of our "natural classification" by means of the analysis of the pure double chlorides of osmium with ammonium and potassium, $(NH_4)_2OsCl_6$ and K_2OsCl_6. Both these salts were obtained in well-formed octahedral crystals, of deep red colour while immersed in their solutions, but appearing deep black with a bluish reflection when dry, and yielding bright red powders on pulverization. The method of analysis consisted in reducing the double chlorides in a current of hydrogen: in case of the ammonium salt the spongy osmium which remained after reduction was weighed, and the expelled ammonium chloride and hydrochloric acid caught in absorption apparatus, and the total chlorine estimated by precipitation with silver nitrate. In case of the potassium salt the expelled hydrochloric acid was absorbed and determined, and the metallic osmium left after removal of the potassium chloride by washing was weighed. The mean value yielded by all these various estimations is 191·1, thus placing osmium in its proper place before iridium, and removing the last striking exception to the "law of periodicity."

AT a recent meeting of the Washington Society of Anthropology, Mr. H. M. Reynolds read a paper on Algonquin metalsmiths. He expressed the opinion that the working of the copper-mines of Lake Superior is not of such high antiquity as has been supposed, and that it may have been continued until comparatively modern Indian times.

SOME time ago the Smithsonian Institution issued inquiries as to the existence and geographical distribution of "rude and unfinished implements of the Palæolithic type." The *American Naturalist* says that responses have been received from thirty States and Territories. The implements already noted amount to between six and seven thousand, and their distribution extends nearly all over the United States. Several hundreds of implements—none of which seem to have been found in the mounds—have been sent to the Institution. The object of the Institution in undertaking this investigation was to determine whether there was in America a Palæolithic Age, and, if so, whether it had any extended existence.

THE Free Public Libraries and Museum of Sheffield seem to be in a most flourishing condition. According to the last Report, which has just been sent to us, there has been a steady increase in the number of books issued. The number issued during the year ending August 31, 1887, was 410,395. The number issued during the previous year was 399,653, so that there was an increase of 10,742.

MESSRS. LONGMANS, GREEN, AND CO. have sent us a series of their test cards in mechanics, packed in neat little cardboard cases. The questions on the many and various branches of the subject are arranged in three stages. Each stage consists of about thirty cards with six questions on each, and is supplemented by cards containing the answers to all the numerical questions. The questions are excellently chosen, and are arranged in an intelligible and progressive order.

A CAREFUL and very valuable bibliography of the works of Sir Isaac Newton, with a list of books illustrating his life and works, by G. J. Gray, has just been issued by Messrs. Macmillan and Bowes, Cambridge. The bibliography is divided into ten sections: (1) collected editions of works; (2) the "Principia"; (3) "Optics"; (4) "Fluxions"; (5) "Arithmetica Universalis"; (6) minor works; (7) theological and miscellaneous works; (8) works edited by Newton; (9) memoirs, &c.; (10) index.

A NEW edition of the late Prof. Humpidge's translation of Dr. Hermann Kolbe's "Short Text-book of Inorganic Chemistry" (Longmans) has been issued. The greater part of this edition was prepared by Dr. Humpidge last summer. Being unable, owing to failing health, to complete the task of revision, he asked Prof. D. E. Jones, of the University College, Aberystwith, to undertake it, and to see the book through the press.

A REPORT, with admirable illustrative maps, on the geology and natural resources of part of Northern Alberta, and the western parts of the districts of Assiniboia and Saskatchewan, by Mr. J. B. Tyrrell, Field Geologist of the Geological Survey of Canada, has just been published at Montreal. The Report is, to a certain degree, preliminary, but the author hopes that, for the present at all events, it may suffice as a guide to the extent, position, and character of the mineral wealth of the district.

AN interesting paper by Mr. Tyrrell, giving an account of the journeys of David Thompson in North-Western America, has been issued at Toronto. It was read lately before the Canadian Institute, and is published in advance of the Proceedings by permission of the Council. The materials for this narrative are contained in Mr. Thompson's field note-books and journals, which are preserved in the office of the Crown Land Department of Ontario. Mr. Thompson died in 1857 at the age of eighty-seven.

MR. LELAND will shortly send to the printer his work on "Americanisms," which will follow on the "Dictionary of Slang, Jargon, and Cant" now in the press. It will contain much folk-lore in the form of proverbs, songs, and popular phrases, and also the etymology and history of the words, as far as they could be traced. The work will include an account of American dialects, such as Pennsylvanian Dutch, Chinook, Creole, and Gumbo. A number of American scholars will deal with special subjects.

WE have received a copy of the *Tōyō Gakugei Zasshi* (the *Eastern Science Journal*), printed in Japanese characters. This magazine is published monthly, and is edited by a committee, most of whose members are Professors of the Imperial University at Tokio. Nearly 3000 copies of each number are sold.

THE first part of the second volume of the Journal of the College of Science, Imperial University, Japan, has been sent to us. The contents include, besides a mathematical paper, in German, by Dr. P. R. Fujisawa, the following articles in English: on the composition of bird-lime, by Dr. E. Drivers, F.R.S., and Michitada Kawakita; on anorthite from Miyakejima, by Yasushi Kikuchi; the source of *Bothriocephalus latus* in Japan, by Dr. Isao Ijima; and earthquake-measurements of recent years, especially relating to vertical motion, by S. Sekiya.

MESSRS. D. C. HEATH AND CO. (Boston) will publish at once Compayre's "Lectures on Pedagogy: Theoretical and Practical," a companion volume to their Compayre's "History of Pedagogy." It is translated and annotated by Prof. Payne, of the University of Michigan.

PROF. J. VIOLLE has just issued the first part of the second volume of his "Cours de Physique." The present part relates to acoustics.

WE reprint from *Science* of June 1, 1888, the following suggestive paragraph:—"The Committee of the House of Representatives on acoustics and ventilation has actually reported favourably a Bill appropriating seventy-five thousand dollars to subsidize a man who thinks he can construct a steel 'vacuum' balloon of great power. He is to be allowed to use the facilities of one of the navy-yards for the building of his machine, and is to have the money as soon as he has expended seventy-five thousand dollars of private capital upon his air-ship. One of the mathematical physicists of Washington was asked by a member of Congress whether such a balloon could be successfully floated. He set to work upon the problem, and here are some of his results, which are rather curious:—A common balloon is filled with hydrogen gas, which, being lighter than air, causes the balloon to rise and take up a load with it. But, as the pressure of the gas within is equal to the pressure of the atmosphere without, no provision other than a moderately strong silk bag is required to prevent collapse. The inventor of the proposed steel balloon hopes to gain greater lifting-power by using a vacuum instead of gas, the absence of substance of any kind being lighter than even hydrogen gas. But he has to contend with the tendency of the shell to collapse from the enormous pressure of the atmosphere on the outside, which would not be counterbalanced by anything inside of it. The first question which presented itself was, How thick could the metal of the shell be made, so that the buoyancy of the sphere, which would be the most economical and the strongest form in which it could be constructed, would just float it without lifting any load? The computations showed that the thickness of the metal might be ·000055 of the radius of the shell. For example: if the spherical shell was one hundred feet in diameter, the thickness of the metal composing it could not be more than than one-thirtieth of an inch, provided it had no braces. If it was thicker, it would be too heavy to float. Now, if it had no tendency to buckle, which of course it would, the strength of the steel would have to be equivalent to a resistance of more than 130,000 pounds to a square inch to resist absolute crushing from the pressure of the air on a cross-section of the metal. Steel of such high crushing-strength is not ductile, and cannot be made into such a shell. If the balloon is to be braced inside, as the inventor suggests, just as much metal as would be used in constructing the braces would have to be subtracted from the thickness of that composing the shell. Of course, such a shell would buckle long before the thickness of the metal of which it was composed was reduced to ·000055 of its radius. In other words, it is mathematically demonstrated that no steel vacuum balloon could be constructed which could raise even its own weight. This is an illustration of how intelligently Congress would be likely to legislate on scientific matters unguided by intelligent scientific advice."

THE additions to the Zoological Society's Gardens during the past week include two Pig-tailed Monkeys (*Macacus nemestrinus* ♂ ♀) from Java, presented by Mr. C. W. Ellacott; a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Mr. J. Wiltshire; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by Mrs. Gleig; two Spotted Cavys (*Cœlogenys paca* ♂ ♀) from South America, presented by Mr. W. H. Stather; a Mauge's Dasyure (*Dasyurus maugæi*) from Australia, presented by Mr. H. R. Brame; three Abyssinian Sheep (*Ovis aries*, var.) from Abyssinia, presented by Mr. A. J. Baker; two Pallas's Sand Grouse (*Syrrhaptes paradoxus*) from the Island of Tiree, Argyllshire, presented by Lieut.-Colonel Irby and Captain Savile Reid, F.Z.S.; a Wapiti Deer (*Cervus canadensis* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE CONSTANT OF ABERRATION.—In the year 1862, Prof. J. S. Hubbard commenced a series of observations of α Lyræ with the prime vertical instrument of the Washington Naval Observatory, which was continued by either Profs. Newcomb, Harkness, or Hall until 1867. The purpose of these observations had been to obtain corrections to the assumed values of the constants of nutation and aberration, and to afford an absolute determination of the annual parallax of the star. The series was not continued for a sufficient period for the first purpose; and Prof. Asaph Hall, when engaged on the determination of the parallax of α Lyræ by another method, found that these observations would give it a small negative value. From this and other circumstances he was at that time induced to think the observations would not repay the trouble of a careful discussion; but recently, reflecting that they had been skilfully designed, and carried out with care, he resolved to ascertain the result they would furnish for the constant of aberration. The observations commenced 1862 March 25, and extended to 1867 April 25, and were 436 in number. The mean resulting value of the parallax is—

$$\pi = -0''\cdot079 \pm 0''\cdot0134,$$

whilst

$$\text{Constant of aberration} = 20''\cdot4506 \pm 0''\cdot0142,$$

with an average probable error for a single observation of $\pm 0''\cdot174$.

Adopting a parallax of $+0''\cdot15$, the result would be—

$$\text{Constant of aberration} = 20''\cdot4542 \pm 0''\cdot0144.$$

Prof. Hall prefers this latter result, notwithstanding the uncertainty as to the true parallax of the star. The negative result obtained for the parallax may probably be due to the fact that the coefficient of parallax obtains its extreme values in January and July, when the mean temperature is likewise at its extreme points; the January observations also are made in daylight, but the July at night, which would tend to produce a systematic difference in the method of observing. The coefficient of aberration, on the other hand, has its greatest values in April and October, when the conditions of observation will be nearly the same.

The above value of the constant of aberration gives, for the solar parallax—

$$\pi = 8''\cdot810 \pm 0''\cdot0062,$$

Hansen's values of the mean anomaly of the earth, and eccentricity of its orbit being assumed, together with Clarke's value for the equatorial radius, and Michelson and Newcomb's determination of the velocity of light, viz. 186,325 miles per second.

THE MARKINGS ON MARS.—The observations of M. Perrotin at Nice, and M. Terby at Louvain, and, in England, of Mr. Denning at Bristol, have confirmed the presence on the planet of most of the "canals" or narrow dark lines which were discovered by M. Schiaparelli in 1877, and at subsequent oppositions. M. Perrotin has also been able to detect, in several cases, the gemination or doubling of the canals, and M. Terby has observed the same phenomenon in one or two cases, but with much greater difficulty than in the opposition of 1881–82. But some curious changes of appearance have been noted. An entire district (Schiaparelli's *Lybia*) has been merged in the adjoining "sea," *i.e.* its colour has changed from the reddish hue of the Martial "continents" to the sombre tint of the "seas." The district in question is larger than France. To the north of this district a new canal has become visible, and again another new canal has appeared to traverse the white North Polar cap, or, according to M. Terby, to divide the true Polar cap from a white spot of similar appearance a little to the south of it. With the exception of these changes, the principal markings, both light and dark, are those which former oppositions have rendered familiar.

COMET 1888 *a* (SAWERTHAL).—The following ephemeris for Berlin midnight is by Herr Berberich (*Astr. Nach.*, No. 2838), from elliptic elements which he has found for it, and which closely resemble those of Prof. Boss given in NATURE of May 24 (p. 88):—

1888.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
June 23	0 55 11	46 11·5 N.	0·2760	0·3129	0·042
25	0 57 1	46 40·5			
27	0 58 42	47 8·9	0·2887	0·3173	0·039
29	1 0 16	47 36·6			
July 1	1 1 42	48 3·7	0·3009	0·3212	0·036
3	1 3 0	48 30·2			
5	1 4 9	48 56·0	0·3127	0·3247	0·033
7	1 5 9	49 21·2			
9	1 6 1	49 45·7	0·3241	0·3278	0·031
11	1 6 44	50 9·6			
13	1 7 18	50 32·8 N.	0·3352	0·3306	0·029

The brightness at discovery is taken as unity.

THE Kazan Observatory has celebrated its "Jubilee" by publishing an interesting report about its activity since it was founded by Littrow fifty years ago. The mapping of the stars between 75° and 80°, which was begun by Prof. Kovalsky, was continued and extended by his successor, Prof. Dubyago.

THE Tashkend Observatory has just issued the second volume of its "Works."

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *JUNE* 24–30.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 24

Sun rises, 3h. 46m.; souths, 12h. 2m. 13·7s.; sets, 20h. 19m.: right asc. on meridian, 6h. 14·5m.; decl. 23° 25′ N. Sidereal Time at Sunset, 14h. 33m.

Moon (Full, June 23, 21h.) rises, 19h. 57m.*; souths, 0h. 9m.; sets, 4h. 20m.: right asc. on meridian, 18h. 19·6m.; decl. 21° 5′ S.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. on meridian h. m.	Declination on meridian ° ′
Mercury	5 33	13 25	21 17	7 37·2	19 52 N.
Venus	3 23	11 41	19 59	5 53·7	23 36 N.

GEOGRAPHICAL NOTES.

LIEUTENANTS KUND AND TAPPENBECK have been conducting an expedition into the Cameroons interior during the latter part of 1887 and the beginning of the present year. Starting from Batanga they succeeded in penetrating as far as 12° 30′ W. long., when, being attacked by Soudan Negro traders they were forced to retreat, both of them seriously wounded. They succeeded in tracing the course of the Beundo or Njong River far into the interior, and brought back much information concerning the people and the products of the country. With regard to general results, they found that the water-parting between the rivers that discharge in the Cameroons region and those that flow into the Congo Basin lies not near the coast as has hitherto been supposed, and therefore it is hoped that a navigable route may be discovered that will lead well into the interior. The water-parting between the left tributaries of the Binué and the rivers in the German Cameroons also lies far in the interior. The division between the Soudan Negroes and the Bantus is not to be looked for in the direction of Adamawa, but southwards is formed by the Zannaga River and eastwards lies at a distance of 150 miles from the coast. Lieutenants Kund and Tappenbeck assert that the area of Mohammedan influence extends much farther south than has hitherto been thought. No signs of volcanic action have been met with as far as the Zannaga River or in the mountains to the north. The profile which accompanies the report shows a coast plain about 70 feet high, succeeded by a sharp slope rising to a height of from 3000 to 4000 feet, beyond which the country slopes gradually to the inner African plateau, about 2500 feet above the sea.

THE June number of Petermann's *Mitteilungen* is mostly occupied with a memoir by Dr. Supan on "A Century of African Exploration," written in commemoration of the centenary of the British African Association, founded in June 1788. Dr. Supan traces the gradual opening up of the continent and its various regions, the text being illustrated by a series of most instructive maps. In indicating what yet remains to be done, Dr. Supan maintains that it is a mistake to assert that the days of pioneer exploration are over. He shows that while a few patches have been surveyed with some care, while of others we have a general knowledge, and while in other regions lines of travel have been run through, there are great regions that still remain absolutely blank. In the north, in the region of the Sahara, which has been so long known to Europe, the blanks are almost greater than elsewhere, leaving ample room for pioneer work, which may very well be carried on alongside of more minute exploration.

TECHNICAL INSTRUCTION.[1]

IN celebrating as we are now doing the fifty-first annual meeting of the Yorkshire Union of Institutes, one's thoughts naturally revert to the foundation of that Union and to the educational progress which our country has made since the earlier years of the century; and round these thoughts will gravitate recollections of the life and labours of your revered President,

[1] Address delivered by Sir Henry Roscoe, M.P., F.R.S., at Castleford, on Wednesday, June 20, on the occasion of the fifty-first annual meeting of the Yorkshire Union of Mechanics' Institutes.

Sir Edward Baines, for in him we have a living picture of the history of the educational progress of the century. Truly, he has been a witness, and an active witness, of English educational reform from his earliest years, nor have his efforts in the great cause from that time forward ever ceased. Was he not even as a boy in Leeds so long ago as 1809 an earnest listener to the expositions of one who may be justly regarded as the founder of our present system of national education, I mean Joseph Lancaster? The name of Baines, again, is intimately connected with those of Birkbeck and Brougham in the great work of founding mechanics' institutes.

The English character is ever prone to consecutive action, sudden revolutions are contrary to its spirit, and this characteristic is evidenced by the present phase of interest in so-called technical education, for this is doing nothing more than carrying out in accordance with the necessities of the hour the old principle enunciated by Birkbeck, Brougham, and Baines in 1825 in the founding of mechanics' institutions, which have for their object the teaching to our workmen the principles of art and science which underlie the trades they practise. This, too, is our definition of technical instruction. We do not attempt to teach trades, but the principles, artistic or scientific, upon which these trades depend. The school can teach how to make the best article, how to apply the principles which lie at the foundation of the manufacture. The workshop, on the other hand, teaches what the workshop alone can teach—how to produce the article most economically. This I take to be the essential distinction between school teaching and workshop practice. The boy at school learns how to do the work well, the man at the factory or shop must learn to do it not only well but most cheaply. If we keep these two parts of the question separate, give to the school what belongs to the school, and to the workshop what belongs to the workshop, we shall avoid all conflict between the so called theorist and the practical man, we shall preserve what is greatly to be prized, our English workshop experience, but add thereto a knowledge of principles which have hitherto been greatly wanting. Each does necessary work; what we desire and need to develop and to foster is the proper union of theory and practice, without which the supremacy in manufacturing industry, the chief glory and mainstay of our country, will be endangered in the industrial warfare in which all civilized nations are now engaged.

This, then, is the problem which Baines sought to solve, and which your Union and all ardent educationists of the present day are striving to accomplish. For this end we now seek Government aid, and are asking for national recognition of a national necessity. What else is the meaning of the Bills for the promotion of technical education now before Parliament? We ask simply for powers to develop and to strengthen the work which mechanics' institutes were founded to accomplish. We desire to carry on that work on sound lines; that, whilst asking for Imperial aid and for the imprimatur of a national system, we shall be left to decide for ourselves the exact mode of carrying out that system which each locality and each special industry knows is best adapted to satisfy its peculiar requirements. These should be the main objects of any Technical Bill. Are these objects properly put forward, and are these conditions properly safe-guarded in the Government Technical Bill now before Parliament? This is the pressing question of the hour. It is for you, and for similar associations throughout the length and breadth of the land, to say whether this is so or not, to satisfy yourselves on this point, and to urge your representative in Parliament—than whom none is more willing or more able to assist you—to see that your claims and opinions on this subject are made known to the Government which is responsible for bringing this great subject forward For, gentlemen, it is a great question, one which lies at the foundation of the future welfare—I had almost said the future existence—of the nation.

May I, then, venture to call your attention to one or two of the salient points in this Bill, and to point out to you what I consider some of its valuable provisions as well as some of its defects? In the first place, then, the chief and leading principle of the Bill is the recognition that the time has arrived for giving national aid, whether from local rates or from Imperial sources, for the promotion of technical instruction. The establishment of this principle is one, I venture to think, of the highest possible importance, which if once admitted may well cover a multitude of minor defects. Still, every benefit may be purchased too dear, and it is well to look at the conditions with which this concession to public opinion is coupled. Here I am speaking to educationists, but I am also speaking in Yorkshire and to Yorkshiremen, who have always upheld, and especially at the present moment do uphold, the standard of Liberal opinion in political as well as in educational matters, and I therefore feel that in expressing my opinion against certain conditions attached to the Bill—conditions which are diametrically opposed to the ideas and principles upon which the Liberal party has always acted—I say in expressing these objections I may claim your support as well as your attention.

Clause 2 of the Bill makes it compulsory on every School Board adopting its provisions as to technical instruction—that is, upon every School Board undertaking to rate its district to the limited penny in the pound—to aid the supply of technical instruction in any other public elementary school not under its management in like manner as it aids the supply of such instruction in its own schools. This clause, which as you all will see may be most sweeping in its effects, must be entirely rejected; indeed, it could not stand one hour's scrutiny in the House of Commons, for it offends against the cardinal principle that those who pay the rates should have a voice, either directly or indirectly, in the spending of them, and this is not provided for. But whilst strongly objecting to this compulsory clause—the only compulsory one in the Bill—I, for one, am willing to consider, and to deal fairly with, the just claims of the voluntary schools; for although I am a believer in the Liberal creed, I am before all things an educationist, and I cannot forget that if we are to have our children made more fit for succeeding in the modern battle of life, we must endeavour to bring to bear upon them all, without distinction of creed or of party, the lever which will raise them in the social scale and enable them to use their heads and their hands to their own benefit, and therefore to that of the nation of which they form the units.

Hence, remembering that more than one-half of our population are educated in voluntary schools, and that in many localities these schools are the only ones in existence, and moreover that they are doing excellent educational work, I, speaking for myself, whilst strongly opposed to any compulsory powers, do not feel the same difficulty in admitting the provisions of the first clause in the Bill by which "any School Board in England may from time to time supply, or aid the supply of, such manual or technical instruction or both, as may be required, for supplementing the instruction in any public elementary school in its district, whether under its own management or not." This clause, you will perceive, enables School Boards if they think fit to assist voluntary schools in their districts by aid from the rates for the special purposes of technical instruction, and through the School Board the ratepayers have a voice as to whether their rates shall or shall not be thus spent. But here comes in the limiting clause that not more than 1*d.* in the pound shall be spent. I object to this limit. It will obviously be very difficult for any School Board to ascertain how far the expenses of giving technical instruction can be accurately defined, and I should prefer to leave the amount spent on this object to the good sense and judgment of the locality as represented by the School Board. But how about districts which possess no School Board? Are they to be left out in the cold? No. Provision is made in a further clause by which any local authority having adopted the Free Libraries Acts may hand over to the voluntary schools in its district a sum not exceeding 1*d.* in the pound for the purpose of supplying technical education to be given in its district public elementary schools. Here again the clause is a permissive one only, and the local authority as representing the ratepayers is the judge of whether and how far such aid is to be given. I do not like the plan of mixing up the vexed question of free libraries with that of technical education, and should much prefer the names of the authorities to be simply scheduled, as I see grave objections to the necessary *plébiscite* in districts which have not already adopted the Acts. Still I do not know that on this account I should wish to see the Bill rejected.

Another grave defect in the Bill is a limit is placed on the teaching of technical subjects in Board schools at the seventh standard. This deals a fatal blow at the higher elementary schools. Thus in the Central School in Manchester at the present moment no fewer than 500 scholars who have passed Standard VII. are now learning the sciences—subjects included within the term technical instruction. These scholars cannot continue thus to be taught under the Bill. We must have a similar provision introduced to that in the Scotch Bill, by which the Boards are empowered to use the rates for the maintenance of higher-grade schools; and these matters must be attended to if we are to have a Technical Bill worthy of the name. The higher technical education, as that given in the Colleges, may be assisted by rates levied by local authorities or by Imperial grants, in addition to those made now by the Department. All acknowledge the importance of this higher training. If the head is not educated, the hands are apt to get into mischief. Hence, as these University Colleges can never be self-supporting, it is greatly to be hoped that they will receive that national aid which their importance to the State demands.

But we have a second Bill before the House of Commons—one introduced by myself on behalf of the National Association for the Promotion of Technical Education. I naturally prefer the provisions of my own Bill to those of the Government. They are much simpler, less clogged and hampered by conditions, and confer the same benefits as the Government Bill proposes to confer, with one exception only, viz. aid from the rates to voluntary schools, for to this many of my friends are strongly opposed; but, so far as I am myself concerned, I am free to admit that I should not object to see the difficulty settled by permissive powers being given to the School Boards to aid voluntary schools in their district, just as it is proposed that local authorities shall have power to do the same where no School Boards exist; for, as I have pointed out, the ratepayers have it in their power to refuse such payments by electing members who will oppose such an application of the rates.

Now, to turn to the more immediate question relating to your Union, you may, I think, be gratified with the results of your fifty-one years' work. You can look back upon half a century of admirable endeavour. You have now 260 institutions in union, containing upwards of 500,000 members and 14,000 technical students. You have spent half a million of money in buildings contributed by voluntary subscriptions, with the exception of 1 per cent. derived from S.K. grants for building. All the members of your committees are unpaid, and many of them have been at work for you all their lives. Your claims for national aid are therefore high, and such aid is much needed, for, though the progress you have made is great, you have not nearly accomplished all that has to be done. We want continuation evening schools established on a new and generous basis. We want a new and more elastic evening school code. We want to emancipate from the rigid lines and requirements of payment on individual results. We want an attendance and merit grant for evening continuation schools—say 12*s*. per head for attendance of sixty nights to insure good and continuous teaching. Above all, we wish that existing institutions should be rendered effective. The 260 institutes are in existence, but need help.

When we look abroad we see that both Governments and municipalities vie with each other in aiding technical schools. They are proud to do so, for they know their value. "Do you suppose," said an intelligent German to me, "that we, weighted as we are with heavy taxation for our military and civil services, would willingly further tax ourselves for the purposes of technical schools unless we were convinced that the outlay will repay us over and over again?" This is German opinion, and it is the opinion which we need to inculcate in the minds of our own people, for then we shall get what we want.

Nor need we be ashamed of the beginnings which we have already made; many of our existing institutions will bear favourable comparison with Continental models. Take Huddersfield for example; the school there exactly meets the requirements of the district, and it has already exerted a very marked and beneficial influence on the trades of the district, especially as concerns dyeing and design. This school cost £20,000, all raised by voluntary effort, but though doing excellent work it is heavily in debt, and its friends have difficulty in raising funds to keep it going—not for lack of pupils, for the school is largely attended, but for the reason that such higher schools cannot be self-supporting, and the greater the number of pupils the greater the cost. Surely, if our people understood their true interests as well as our neighbours and competitors do, they would not rest until such an institution is placed in a position to do all it can to raise the condition of their industries by supplanting the too common and worn-out rule of thumb by scientific knowledge always new and always productive. Then again at Yeadon, a small place, you have a school which cost £7000 to build, and in which 350 students are being instructed. But here, too, funds are urgently needed to carry on the work. Surely there ought not to be many who grudge spending a penny in the pound on such objects. In Castleford itself, your Mechanics' Institute has done during its forty years of life, and is now doing, good work. The building is, however, too small for the requirements of the day; your numbers have increased from 80 to 210, and the necessary appliances for teaching science and technology are deficient. Let us hope that when the Technical Bill becomes an Act, Castleford will be one of the first to take advantage of its provisions.

But you may ask, What good will come to our leading industries here—coal and glass—by your technical education? How shall the employers and employed benefit therefrom? In the first place, then, there is no industry in which the value of even a little scientific training is so important for both masters and men as in that of coal-getting. Such a training may, for instance, be, and indeed has often been, the means of saving hundreds of valuable lives. One ignorant man may place in jeopardy or even sacrifice by a single careless act the lives of his comrades, an act which no one acquainted with the properties of explosive gases would dare to commit. In a thousand other ways scientific knowledge—which after all is only organized common-sense—will help all concerned in this great industry. So again in glass-making, how great is the aid given by scientific and artistic knowledge. What a step was the introduction of the Siemens regenerative tank furnace, and how much more remains to be achieved. Then your bottle trade might, by the application of artistic knowledge, be made the foundation of a higher and more tasteful industry which might successfully compete with the wares of Bohemia and Venice. Why not? Are not our workmen both mentally and physically superior to the foreigner? I believe them to be so. They only need teaching, and that we have hitherto withheld from them.

It has been well said that whilst we have confined our attention to improving our machines, the Germans have devoted themselves to educating their men. Let us lose no time in following their lead. "What we fear," said one of the masters to me, "is not either free trade or protection. What we fear is that some day you English will wake up to the necessity of educating your manufacturing population as we do, and then with your racial and physical advantages it will become difficult, if not impossible, for us to compete with you." Let us, then, take to heart the old adage that victory comes to the strong, but remember that it is not to the bodily strong, but only to the strong mentally and morally that the victory comes. Let us see that in this struggle for existence our people are healthy and vigorous in all these three essentials, and act upon the true and eloquent words of Huxley, "You may develop the intellectual side of a people as far as you like, and you may confer upon them all the skill that training and instruction can give, but if there is not underneath all that outside form and superficial polish the firm fibre of healthy manhood and earnest desire to do well, your labour is absolutely in vain."

THE INTERNATIONAL GEOLOGICAL CONGRESS.

ADMIRABLE arrangements have been made for the London meeting of the International Geological Congress, from September 17 to 22 next. The following details are taken from a printed letter signed by the General Secretaries, Mr. J. W. Hulke and Mr. W. Topley. The meetings will be held in the rooms of the University of London, Burlington Gardens, where accommodation for the Council, Committees, Exhibition, &c., has been granted by the Senate of the University. There is a refreshment-room in the building, and there are several restaurants and hotels in the immediate neighbourhood. Arrangements will be made at one of these restaurants for a room to be set apart for the social meetings of members of the Congress. The opening meeting of the Congress will take place on Monday evening, September 17, at 8 p.m., when the Council will be appointed, and the general order of business for the session will be determined. The ordinary meetings of the Congress will be held on the mornings of Tuesday, the 18th, and succeeding days, beginning at 10 a.m. In the afternoons there will be visits to Museums, or to places of interest in the neighbourhood of London. Arrangements for the evenings will be made at a later date. The ordinary business of the Congress will include the discussion of questions not considered at Berlin, or adjourned thence for fuller discussion at the London meeting. Amongst these are: the geological map of Europe; the classification of the Cambrian and Silurian rocks, and of the Tertiary strata; and some points of nomenclature, &c., referred to the Congress by the International Commission. Miscellaneous business will also be considered. In addition to these questions, the Organizing Committee proposes to devote a special sitting to a discussion on the Crystalline Schists. An Exhibition will be held during the week of the Congress, to which geologists are invited to send maps, recent memoirs, rocks, fossils, &c. Foreign members of the Congress are invited by the Council of the British Association to attend the meeting of that Association at Bath. During the week when the Association meets, there will be short excursions in the neighbourhood of Bath, and longer excursions will be made after the meeting. At these excursions excellent sections of the Lower Secondary and Upper Palæozoic rocks will be visited. Excursions will take place in the week after the meeting of the Congress (September 24 to 30). The number of these will depend upon the number of members desirous of attending, and upon the districts which they most wish to visit. The excursions at present suggested are :—(1) The Isle of Wight (visiting the Ordnance Survey Office at Southampton on the way)—Cretaceous, Eocene, Oligocene. (2) North Wales—Pre-Cambrian and the older Palæozoic rocks ; West Yorkshire (Ingleborough, &c.)—Silurian and Carboniferous Limestone. (3) East Yorkshire (Scarborough, Whitby, &c.)—Jurassic and Cretaceous. Should the number of members be so large as to make additional excursions necessary, they will probably be :—(4) Norfolk and Suffolk—Pliocene (Crag) and Glacial beds. (5) To the Jurassic rocks of Central England. The short excursions during the week of the Congress will probably be to Windsor and Eton, to St. Albans, to Watford, to Brighton, to the Royal Gardens at Kew, and to other places of interest. Brief descriptions of the districts to be visited in these excursions will be prepared (with illustrative sections, &c.), and will, if possible, be sent to members before the meeting. The full Report of the London meeting will be issued soon after the close of the session. It will contain, in addition to reports of the ordinary business of the Congress, the Report of the American Committee on Nomenclature (about 230 pp.) ; the Memoirs on the Crystalline Schists (about 150 pp.), and reports of discussion on the same ; and probably a reprint, with additions, of the Report of the English Committee on Nomenclature (about 150 pp.).

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Burdett-Coutts Scholarship in Geology has been awarded to Mr. M. Hunter, B.A., Queen's College.

The degree of M.A. *honoris causâ* has been conferred on Dr. S. J. Hickson, the Deputy Linacre Professor, and on Mr. Wyndham R. Dunstan.

Scholarships in Natural Science are announced for competition, at Merton and Corpus jointly on June 26, at Magdalen on October 9, and at Balliol, Christ Church, and Trinity jointly on November 20. Information may be had from the science tutors of the various Colleges.

A statute is being discussed by Congregation, which will place the biological sciences on the same footing as the physical sciences so far as the examinations for pass degrees are concerned, and it is hoped that the changes to be introduced will increase the numbers of the biological and medical schools.

Mr. F. J. Smith, of the Millard Laboratory at Trinity, has been appointed University Lecturer in Mechanics and Experimental Physics.

CAMBRIDGE.—An amended report on the Natural Science Examinerships has just appeared, but the scheme proposed is very complex. It having been found difficult to get examiners to undertake the honours, and ordinary degree, and M.B. examinations combined, it is proposed to separate the elementary examination work, and appoint two examiners each in elementary chemistry, in elementary physics, and in elementary biology, while two examiners in each subject of the Natural Sciences Tripos are to be appointed as before, and two in pharmaceutical chemistry, for the second M.B. Thus there will be twenty-four examiners in all. The examiners are to be paid a minimum of fifteen, twenty, or thirty pounds each, with a payment of five shillings for each Tripos candidate in their subject, or one, two, and four shillings per candidate in other examinations. Moreover, it is required that all papers and all practical work in honours shall be examined by both examiners in a subject. Both examiners are to be present at all oral work in their subject; and all examiners must be present at the meeting for arranging the class-list for any examination. We prognosticate that the list of examiners, if at all worthy of the University, will not largely consist of non-residents, under the new scheme. The worst mistake perhaps that the University makes is in continuing the one-sided ordinary degree examinations in single subjects, such as geology, botany, and zoology ; for all combined there were only four candidates in the last academical year ; and for these there were six separate examinations provided, though two were not held. The chemistry "special" attracts a number of candidates, who might be much better employed in preparing for the First Part of the Natural Sciences Tripos. It would be far easier to work the Natural Science Examinations if these were abolished. It is absurd to keep up a machinery of examination which is tabooed even by candidates. The Tripos is a success, which the specials are not, and still more liberal payments and regulations ought to be made. It ought to be remembered that the graduates pay heavy degree fees in addition to examination fees.

The examiners for 1888 in the Second Part of the Mathematical Tripos were Edward John Routh, Sc.D., Peterhouse ; James Whitbread Lee Glaisher, Sc.D., Trinity College ; Joseph John Thomson, M.A., Trinity College ; Andrew Russell Forsyth, M.A., Trinity College. The names, in each class and in each division, are arranged in alphabetical order, and not in order of merit. All the candidates passed the Mathematical Tripos, Part I., in June 1887.

Class I.—Division 1.—Baker, B.A., Joh. ; Berry, B.A., Trin. ; Flux, B.A., Joh. ; Mitchell, B.A., Trin. Division 2.—Brown, B.A., Christ's ; Clay, B.A., Trin. ; Iles, B.A., Trin.

Class II.—Little, B.A., Trin. ; Norris, B.A., Joh. ; Peace, B.A., Emman. ; Soper, B.A., Trin.

Class III.—None.

The faint hope that there was till lately that a Geological Museum might soon be begun has been dissipated by the Financial Board having reported that the University has no funds available at present, although the Sedgwick Fund has £19,000 in hand to supplement the University contribution.

The late Sir Charles Bunbury's valuable herbaria have been presented to the University by Lady Bunbury.

At the Annual Scholarship Election at St. John's College, on June 18, the following awards in Natural Science were made :—Foundation Scholarships continued or augmented—Seward, Rolleston, Rendle. Turpin, Groom, d'Albuquerque ; Foundation Scholarships awarded—Hankin, Horton-Smith, Locke, Baily, Simpson ; Exhibitions awarded—d'Albuquerque, Hankin, Horton-Smith, Blackman, Schmitz. In Mathematics, the following awards were made :—Foundation Scholarships continued or augmented—Baker, Flux, Norris, Orr, Sampson, Harris, Rudd, Bennett ; Foundation Scholarships awarded—Palmer, Carlisle, Burstall, Monro, Cooke, Lawrenson ; Exhibitions awarded—Sampson, Harris, Monro, Dobbs, Reeves, Bennett, Burstall, Cooke, Lawrenson, Brown, Finn, Kahn, Salisbury, Schmitz, Shawcross ; Proper Sizarship awarded—Finn. Wright's Prizes to Simpson, Hankin, Blackman, for Science ; and Orr, Burstall, Reeves, for Mathematics. The Herschel Prize to Salisbury, for Astronomy ; the Hockin Prize for Electricity not awarded. The Hutchinson Studentship of £60 a year for two years is awarded to Mr. G. S. Turpin for research in Organic Chemistry ; and the Hughes Prize to Orr (Senior Wrangler) and Brooks (Senior Classic).

SCIENTIFIC SERIALS.

American Journal of Science, June.—Note on earthquake-intensity in San Francisco, by Edward S. Holden. The object of this paper is to obtain an estimate of the absolute value of the earthquake-intensity developed at San Francisco during the American historic period, based on the very complete records collected by Thomas Tennant. The intensity of each separate shock (417 altogether) is assigned on the arbitrary scale of Rossi and Forel. The total average intensity during the 80 years from 1808 to 1888 is found to be nearly equal to the intensity of 28 separate shocks as severe as that of 1868, and the 417 shocks of known intensities correspond to 33,360 units of acceleration.—On the relations of the Laramie Group to earlier and later formations, by Charles A. White. The author's further studies of this group, by some geologists referred to the Tertiary, by others to the Cretaceous ages, lead to the conclusion that the upper strata form a gradual transition from the latter to the former, while there is strong presumptive evidence of the Cretaceous age of the greater part of it.—The gabbros and diorites of the "Cortlandt Series" on the Hudson River near Peekskill

New York, by George H. Williams. With this paper the author concludes for the present his elaborate petrographic studies of the extremely varied massive rocks of the "Cortlandt Series," as it has been designated by Prof. J. D. Dana. He treats in detail the gabbro, diorite, and mica-diorite varieties of norite occurring chiefly in the south-western portion of the area.—Three formations of the Middle Atlantic slope (continued), by W. J. McGee. In this concluding paper the whole subject of the Columbia formation is recapitulated, the general conclusion being that it is much older than the moraine-fringed drift-sheet of the North-Eastern States, and that while th evertebrates of its correlatives suggest a Pliocene origin, both stratigraphy and the invertebrate fossils prove that it is Quaternary. Thus the Columbia formation not only enlarges current conceptions of Quaternary time, and opens a hitherto sealed chapter in geology, but at the same time bridges over an important break in geological history, between the Tertiary and Quaternary epochs.—A comparison of the elastic and the electrical theories of light with respect to the law of double refraction and the dispersion of colours, by J. Willard Gibbs. The main object of this paper is to show the great superiority of the electric over the elastic theories of light as applied to the case of plane waves propagated in transparent and sensibly homogeneous media. The phenomena of dispersion here studied corroborate the conclusion which seemed to follow inevitably from the law of double refraction alone.—Mr. Henry J. Biddle contributes some valuable notes on the surface geology of Southern Oregon, visited by him during the summer of 1887.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 7.—"An Additional Contribution to the Placentation of the Lemurs." By Prof. Sir Wm. Turner, Knt., M.B., LL.D., F.R.S.

In 1876 the author contributed to the Royal Society a memoir "On the Placentation of the Lemurs," which was published in the Philosophical Transactions of that year (vol. clxvi. Part 2). The gravid uteri which he examined and described were from specimens of *Propithecus diadema*, *Lemur rufipes*, and *Indris brevicaudatus.*

In April of the present year he received from Mr. F. E. Beddard, Prosector to the Zoological Society of London, the gravid uterus of a Lemur, which was *Lemur xanthomystax.*

The examination of this gravid uterus confirmed the conclusions to which both Alphonse Milne Edwards[1] and the author had arrived independently from previous investigations, that the placenta in this important group of animals is diffused and non-deciduate, and that the sac of the allantois is large and persistent up to the time of parturition. In these important respects, therefore, the Lemurs, are, in their placental characters, as far removed from man and apes as it is possible for them to be.

Although the author is not disposed to attach too much weight to the placenta as furnishing a dominant character for purposes of classification, yet he cannot but think that animals which are megallantoid, non-deciduate, and with the villi diffused generally over the surface of the chorion, ought no longer to be associated in the same order with animals in which, as in the apes, the sac of the allantois early disappears, and the villi are concentrated into a special placental area, in which the fœtal and maternal structures are so intermingled that the placenta is highly deciduate. Hence he is of opinion that the Lemurs ought to be grouped apart from the Apes in a special order, which may be named either with Alphonse Milne Edwards *Lemuria*, or with Victor Carus and others *Prosimii.*

The fœtus possessed an imperfect covering, external to the hairy coat, and quite independent of the amnion, composed of a cuticular membrane. It corresponded with the envelope named by Welcker *epitrichium*, and described both by him and by the author as present in *Bradypus* and *Cholopus*. But it occurred in the fœtus both of *Lemur xanthomystax* and *Propithecus diadema* in flakes and patches, and not as a continuous envelope as in the Sloths.

Physical Society, May 26.—Mr. Shelford Bidwell, F.R.S., Vice-President, in the chair.—The following communications were read:—Note on the governing of electromotors, by Profs. W. E. Ayrton and J. Perry. In a paper read before the Society of Telegraph-Engineers in 1882 the authors deduced the conditions of self-regulation of electromotors for varying load when supplied either at constant potential or with constant current. The conditions involved "differential winding," *i.e.* the use of a shunt motor with series demagnetizing coils. With this arrangement fairly good regulation has been obtained, but owing to want of economy the methods have not been developed further. Since then another arrangement, in which a simple shunt motor is used, and a few accumulators placed in series with the armature, has been devised for working in a constant current system. By means of a suitable switch, the accumulators can be charged when the motor is at rest. On the assumption that the E.M.F. of motors is given by $E = n(p + tZ)$, where n = speed, Z = number of turns on magnets, and p and t are constants, it is shown that the speed at which a motor will govern is given by

$$n = \frac{z + a + a'}{t},$$

and the constant current

$$C = \frac{e - np}{a + a'},$$

where z and a are the resistances of the shunt and armature respectively, and e and a' the E.M.F. and resistance of the accumulators. Since a and a' may be small and np not large, the value of e need not be great to give a considerable value for C, and thus only a small number of accumulators will be required.—On the formulæ of Bernoulli and Haecker for the lifting-power of magnets, by Prof. S. P. Thompson, read by Prof. Perry. The formulæ referred to are $P \propto \sqrt[3]{W^2}$ and $P = a\sqrt[3]{W^2}$ respectively, where P = lifting-power, W = mass of magnet, and a a constant depending on the material and shape of the magnet. These formulæ, the author shows, are equivalent to saying that the lifting-power of magnets in which the magnetic induction, B, has been carried to an equal degree, is proportional to the polar surface, and that Haecker's coefficient a is proportional to B^2 through the surface. Assuming the induction uniform over the surface, it is shown that

$$P = \frac{1}{8\pi} B^2 A,$$

where A = area of surface, and this gives a very convenient method of determining B from measurements made upon the pull exerted at a given polar surface. If P be measured in kilogrammes and A in square centimetres, the formula for B becomes

$$B = 5000 \sqrt{\frac{P}{A}};$$

and if the measurements be made in pounds and inches, the constant becomes 1317. It will be readily seen that the greater power of small magnets in proportion to weight does not require for its explanation the sometimes alleged fact that small pieces of steel can be more highly magnetized than large ones, for if B be the same, the lifting-power will be proportional to the polar surface, and not to weight, and hence must necessarily be greater relatively to weight in small magnets. In the case of electro-magnets for inductions between 6000 and 16,000, between which the permeability, μ, is approximately given by

$$\mu = \frac{16{,}000 - B}{3 \cdot 2},$$

the lifting-power is shown to be

$$P = A\left(\frac{3 \cdot 2\, Si}{Si + 2 \cdot 56 l}\right)^2,$$

where P is in kilogrammes, A in square centimetres, Si = ampere turns, and l = mean length of the magnetic circuit.—Experiments on Electrolysis; Part ii., Irreciprocal Conduction,[1] by Mr. W. W. Haldane Gee and Mr. H. Holden. An abstract was read by the Secretary. The authors have observed, when strong sulphuric acid is used as an electrolyte, the electrodes being of platinum, that the decomposition nearly ceases, if, by decreasing the resistance in circuit, it is attempted to increase the current beyond a certain maximum. When this condition (called the insulating condition) is arrived at, reversing the current immediately restores the conductivity. Experiment shows that the current density is an important factor, and that the composition,

[1] "Histoire Naturelle des Mammifères de Madagascar," forming vol. vi. chap. ix. of Grandidier's "Histoire de Madagascar."

[1] Irreciprocal conduction is said to occur if a reversal of the direction of a current causes any change in its magnitude.

viscosity, and temperature of the electrolyte, as well as the previous history of the electrode, have considerable influence on the current density at which the insulating condition occurs. The seat of the insulating layer is found to be at the anode; and the authors believe it due to very concentrated acid formed around the electrode, whose specific resistance is very high. Experiments were also made with carbon and gold electrodes, and phosphoric acid, caustic potash, soap, and sodium benzoate were used as electrolytes, the results of which seem compatible with the concentration hypothesis above stated. The paper contains an historical and critical account of allied phenomena, and tables expressing the numerical results obtained by the authors are given.

Linnean Society, June 7.—Mr. Carruthers, President, in the chair.—The following were nominated Vice-Presidents: Mr. F. Crisp, Dr. Maxwell Masters, Dr. John Anderson, Mr. C. B. Clarke.—An exhibition under the microscope of decalcified and stained portions of the test of *Laganum depressum* was then given by Prof. Martin Duncan, who made some very instructive remarks on the structural characters to be relied on for discriminating the species.—Mr. D. Morris, of Kew, exhibited some drawings of a Fungus (*Exobasidium*) causing a singular distortion of the leaves of *Lyonia*, from Jamaica.—A paper was then read, by Mr. H. N. Ridley, on the natural history of Fernando Noronha, in which he gave the general results of his investigations into the geology, botany, and zoology of this hitherto little explored island.

Royal Meteorological Society, May 16.—Dr. W. Marcet, F.R.S., President, in the chair.—The following communications were read:—Report of the Wind Force Committee on experiments with anemometers conducted at Hersham, by Mr. G. M. Whipple and Mr. W. H. Dines. A whirling apparatus, with arms 29 feet radius, was rotated by means of a small steam-engine. On the arms of the whirler four different anemometers were placed. Each experiment lasted fifteen minutes, the steam-pressure remaining constant during the run. For the Kew standard anemometer, with arms 2 feet long, the experiments give a mean value for Robinson's factor of 2·15; and for two smaller instruments the factor is 2·51 and 2·96. Mr. Dine's helicoid anemometer gave very satisfactory results, the mean factor being 0·996.—On the measurement of the increase of humidity in rooms by the emission of steam from the so called bronchitis kettle, by Dr. W. Marcet, F.R.S. The author described a number of experiments which he had made by steaming a room with a bronchitis kettle, and ascertaining the rise and fall of the relative humidity from readings of the dry- and wet-bulb thermometers. He found that the air in the room could not be saturated, the relative humidity not exceeding 85 per cent.

Entomological Society, June 6.—Dr. D. Sharp, President, in the chair.—Mr. Pascoe brought for exhibition a book of fine plates of *Mantidæ*, drawn by Prof. Westwood, which it had been hoped would have been published by the Ray Society.—Mr. E. Saunders exhibited a species of Hemiptera, *Monanthia angustata*, H-S., new to Britain, which he had captured by sweeping, near Cisbury, Worthing. The insect is rather closely allied to the common *Monanthia cardui*, L.—Mr. McLachlan exhibited a species of *Halticidæ*, which had been sent him by Mr. D. Morris, Assistant Director of the Royal Gardens, Kew, who had received them from Mr. J. H. Hart, of the Botanic Gardens, Trinidad, with a note to the effect that they had attacked young tobacco and egg-plants badly in that island. Mr. Jacoby had, with some reserve, given as his opinion that it might possibly turn out to be *Epitrix fuscata*, Duv., a species which had been described from Cuba.—The Rev. H. S. Gorham exhibited a collection of beetles lately captured in Brittany including *Diachromus germanus*, L., *Onthophagus taurus*, L., *Hister sinuatus*, Ill., and other species which are exceedingly rare, or altogether wanting in Britain, and yet occur very commonly in the north of France.—Mr. White exhibited living larvæ of *Endromis versicolora*, from near Bristol, and remarked that when quite young they are nearly black, owing to being very thickly spotted with that colour; the body-colour is green, and after two or three changes of skin the spots disappear. Mr. White also exhibited two preserved larvæ of *Phorodesma smaragdaria*, which he had recently taken, and made some remarks concerning the so-called "case," which this insect is said to construct from the leaves of its food-plant, *Artemisia maritima*. This he did not consider to be really a case, but he had discovered that the larva possessed on its segments certain secretory glands, at the apex of each of which there is a bristly hair; this appears to retain pieces of the plant, which are probably fixed firmly afterwards by means of the secreted fluid. These pieces are very irregularly distributed, and their purpose does not seem quite evident.—Mr. Lewis exhibited about three hundred specimens of the genera *Hetærius*, Er., and *Eretmotus*, Mars. The most remarkable of these was *Hetærius acutangulus*, Lewis, discovered last year by Mr. J. J. Walker near Tangier, and recently taken by him at San Roche, in Spain.

PARIS.

Academy of Sciences, June 11.—M. Janssen, President, in the chair.—A study of the refrigerant mixtures obtained with solid carbonic acid, by MM. Cailletet and E. Colardeau. These researches seem to show that the ether generally used in combination with snow and carbonic acid for the purpose of obtaining intense cold, plays a much greater part than has been supposed in lowering the temperature of the mixture.—Representation of the attitudes of human locomotion by means of figures in relief, by M. Marey. The figure of a runner at a given moment is here reproduced from a relief obtained by M. Engrand by means of the photochronograph. It is pointed out that a continuous series of such figures, obtained by this process, would be of great service in determining for artists and physiologists the successive changes of attitude in running and walking.—Determination of the mean level of the sea, by means of a new instrument, by M. Ch. Lallemand. In a previous note (*Comptes rendus*, May 28, 1888) the principle was described of this apparatus, which is here figured and named the *medimaremeter*. It gives the mean sea-level without any mechanical adjustments, and almost without the need of calculations—On the artificial reproduction of hydrocerusite, on the chemical composition of this mineral species, and on the constitution of white lead, by M. L. Bourgeois. These synthetic researches throw much light on the hitherto problematical nature of hydrocerusite, as well as on the constitution of white lead (ceruse), in which the author distinguishes only two definite substances, both existing in nature—hydrocerusite and cerusite. Analysis shows that the formula of the artificially prepared hydrocerusite is $3PbO,2CO_2,HO$, or $2(PbO,CO_2) + PbO,HO$, which is no doubt that of the natural substance also.—On the variations of the personal equation in the measurement of double stars, by M. G. Bigourdan. Thiele supposes that the personal equation of each observer remains somewhat constant during a "season of observations," and then takes a different value for another period, the duration of the "seasons" varying from a few days to several months. But according to Struve these variations are rapid, occurring in a few hours, and lasting only a single night. The observations of the author tend to show that these apparently contradictory views are capable of being reconciled, both being to a certain extent true.—On the determination of some new rings of Saturn lying beyond those already known, by Dom Lamey. These were first vaguely perceived by the author in 1868, and have been repeatedly observed since February 12, 1884, with the 16 cm. refractor in the clearer atmosphere of the Grignon Observatory. They are four in number, and are visible as well-defined elliptical rings in the regions intermediate between Mimas and Titan, first and sixth satellites of Saturn. The semi-diameter of the planet being taken as 1, the semi-diameter of the rings, measured from the middle of the most intense region, would be $2·45 \pm 0·05$; $3·36 \pm 0·02$; $4·90 \pm 0·50$; $8·17 \pm 0·23$. They were also independently observed by two of the author's fellow-workers, and cannot therefore be explained away as optical illusions due to the terrestrial atmosphere or any other sources of error.—On a point in the history of the pendulum, by M. Defforges, with remarks by M. C. Wolf. In connection with Kater's memoir of 1818, presented to the Royal Society, on the "convertible" pendulum, and his repudiation of de Prony's claim to priority of invention, M. Defforges announces the discovery of some documents in the Ecole des Ponts et Chaussées fully confirming de Prony's claim. M. Wolf, however, points out that these documents (undated, but no doubt written in 1800) were never published, and certainly unknown both to Bohnenberger when he announced the project of a pendulum with reciprocal axes (1811), and to Kater when he rejected de Prony's claim to priority of invention (1818). Hence, although de Prony now appears to have been the precursor, the rights of Bohnenberger and Kater remain intact as discoverers of the principles to which is due the revolution effected in the observations of the pendulum during the present century.—On a correction to be made in Regnault's determinations of the weight of a litre of the elementary gases, by M. J. M. Crafts. The error already pointed out by Lord Rayleigh is here corrected for air, N, H, O, and CO_2.—Experiments with a non-oscillating pendulum, by M. A. Boillot. It is shown that the oscillating pendulum, which in Foucault's experiment demonstrates the movement of the globe, may be used for the same demonstration by suppressing the oscillatory action and operating in a room.—Measurement of the velocity of etherification by means of electric conductors, by M. Negreano. A process is explained for measuring the rapidity of the chemical reactions which take place between certain resisting bodies at the moment their electric resistances become varied. These resistances have been measured according to the method indicated by Lippmann.—On a diamantiferous meteorite, which fell on September 10/22, 1886, at Novo-Urei, in the Government of Penza, Russia, by MM. Ierofeieff and Latchinoff. Analysis of this specimen, weighing 1762 gr., shows that it contains 1 per cent. of very fine carbonado, or diamond dust, besides 1·26 of amorphous carbon. The other chief substances were—peridot, 67·48; pyroxene, 23·82; and nickled iron, 5·45.

BERLIN.

Physical Society, June 1.—Prof. von Helmholtz, President, in the chair.—Dr. Lummer gave an account of experiments which he had made on the determination of the focal length of lenses by the method of Abbe in Jena. The method is based upon the equation $f = \frac{a}{\beta_1 - \beta_2}$; where f is the focal length, a the distance of two objects from the lens, and β_1 β_2 the respective magnifications of their images. The speaker discussed first the way by which Abbe had arrived at the above equation, and then went thoroughly into an explanation of the methods for measuring the amount of magnification of the images. It must suffice here to say briefly that the magnification was measured by a microscope directed along the principal axis of the lens, and at right angles to its surface, the microscope then being moved backwards and forwards, until the upper and lower ends of the image were visible. Prof. von Helmholtz explained that during his physiological-optical researches he had already determined the focal lengths of lenses by the measurements of the magnification, in accordance with the formula given above, admitting at the same time that his methods were perhaps less exact.—Dr. Lummer then gave an abstract of a paper on the movement of air in the atmosphere, which he had recently read before the Academy of Sciences. In solving the problem, he had made use of the principle of mechanical similarities. When the hydrodynamic equation for a given motion is known, it is only necessary to multiply all the factors by n in order to represent the motion in much larger dimensions. Accordingly if the conditions of the occurrence of air currents, such as take place in the atmosphere, have been experimentally determined in the laboratory for 1 cubic metre of air, and if the atmosphere is assumed to be 8000 metres high, then the space, time, and moment must be multiplied by 8000, while on the other hand the internal friction must be taken as being only 1/8000 of that which has been determined by experiment. It follows from this that the internal friction is of very small account; but as against this, the friction of the earth's surface has a considerable influence and cannot be neglected. Supposing a mass of air moving horizontally is considered, then a series of particles of air, which were at the outset vertically each above the other, will finally place themselves along a curve of sines as the result of friction at the earth's surface. Calculation shows that it would require a period of 42,000 years before the motion was reduced to one-half as the result of internal friction. The speaker then considered the atmosphere as made up of rings of air which surround the earth in coincidence with the parallels of latitude: each of these rings of air has its own moment of rotation, which depends on its radius, and is therefore greatest at the equator and least at the poles. If the air which is streaming upwards at the equator were to stream down again to the earth in higher latitudes, it would be moving with a velocity far exceeding that of any known storm, even at the latitude of 30°. Since the internal friction of the air is so small that it may be neglected, the speaker proceeded to point out the other factors which have an influence in slowing down the air as it falls. He regards them as being the vortex motions which take place in the atmosphere at the iscontinuous surfaces of two masses of air moving with different velocities. These vortex motions cause the adjoining layers of the two masses of air to mix, and thus diminish their velocity. This is the explanation of the calms, trade-winds, sub-tropical rains, and other phenomena which occur in the atmosphere. It would occupy too much space to give even a brief statement of how these conclusions are arrived at.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

A Course of Practical Instruction in Botany, Part 1, 2nd edition: Prof. F. O. Bower (Macmillan).—Lessons in Elementary Mechanics, Stage 2: W. H. Grieve (Longmans).—Observations on the Embryology of Insects and Arachnids: A. T. Bruce (Baltimore).—Smithsonian Report, 1885, Part 2 (Washington).—Birdsnesting and Bird-skinning, 2nd edition: M. THURSDAY, JUNE 28, 1888.

THE EARLY CORRESPONDENCE OF CHRISTIAN HUYGENS.

Œuvres Complètes de Christian Huygens publiées par la Société Hollandaise des Sciences. Tome Premier : Correspondance 1638–1656. (La Haye : Martinus Nijhoff, 1888.)

NEVER before, we venture to assert, even in this age of "complete editions," has so colossal a literary monument been raised to the memory of a great man as the edition of the works of Christian Huygens, of which the first instalment now lies before us. In a huge and splendid volume of 621 quarto pages, is contained the correspondence, from his ninth to his twenty-eighth year, of the "young Archimedes," as his friends delighted to call him. Yet out of 2600 documents in the hands of the Commission charged by the Amsterdam Academy of Sciences with the superintendence of the publication, no more than 365 have as yet been printed. Seven additional tomes, at least as massive as that just now issued from the press at the Hague, will be needed to bring to completion the initial section of the comprehensive record. The works of Huygens, edited and inedited, will follow, with an elaborate biography, so that we may safely assume that the present century will not see the end of an enterprise the pecuniary responsibility of which has been generously undertaken by the Scientific Society of Holland.

We have nothing but praise to accord to the manner in which it has so far been conducted. All selective difficulties were indeed spared to the Commission ; for the collection at Leyden was of such exceptional value that their resolution to print everything it contained admitted of no cavil, and was arrived at without hesitation. Room was, however, left for discretion as to the manner of presenting to the public the materials at their disposal ; and it has been wisely exercised. The notes are elucidatory without being obtrusive ; the prefatory remarks are few and to the point ; the indexes (of which there are no less than five) afford a satisfactory clue to a labyrinth of close upon four hundred letters in Latin, French, and Dutch, miscellaneous in their contents, and necessarily chronological in their arrangement. They are of great and varied interest. Scientific history, the dispositions and modes of thought of "men of light and leading" in the seventeenth century, the manners and customs of the time, are all in turn illustrated by them ; above all, their perusal offers singular advantages for studying the development of the powerful and active mind of the protagonist in the life-drama they partially unfold.

Christian Huygens was born at the Hague, April 14, 1629. Every educational advantage which the age could afford was showered upon him. His father, Constantine Huygens, was distinguished as a statesman, a poet, a man of letters, and a musician. Himself a product of the most varied culture, he desired that none of the brilliant faculties early apparent in his two elder sons should rust in disuse. They were accordingly taught to sing and play the lute as well as to compose Latin verses ; they attended the juridical lectures of Vinnius, and studied mathematics under Van Schooten ; they were accomplished in dancing and drawing no less than in Greek, rhetoric, and logic ; they travelled to see the world and improve their manners ; they could, as occasion required, play the courtier, or work as skilled mechanics. The native turn of each was, however, different. Constantine excelled in the lighter branches of literature ; Christian promptly shot ahead of him in geometry. Study and invention went, with him, in this direction, hand in hand. Before he was seventeen, he had begun to strike out original lines of investigation, and the promise of these juvenile essays was discerned, among the first, by Descartes. Mersenne about the same time opened a correspondence with him, and predicted for him greatness beyond that of the towering figure of Archimedes.

He made his *début* in print in 1651 with a treatise on quadratures, to which he appended a refutation of the theorems on the same subject of Gregory of St. Vincent, with the unusual result of gaining (besides many admirers) a friend in the person chiefly interested in the controversy. The little book was received with acclamations of praise. At once and everywhere, the genius of its author was acknowledged. The mathematicians of France, England, and Germany vied with those of Holland in doing him honour. He was lauded as "Vieta redivivus," placed on a level with Pappus and Apollonius, hailed as the great coming light of science. Yet it was not in pure mathematics that his brightest laurels were to be gathered. Many lesser men did more to help on the great revolution in method which signalized his age. He remained, throughout its progress, constant to the ancient models, and looked on, indifferent or averse to changes the full import of which he failed to realize. His extraordinary ability was, however, never more conspicuous than in his successful grappling with problems—such as that of the isochronous curve—unapproachable by geometers of a more common-place type without the aid of the calculus ; and there is reason to think that, had he lived longer, he would have reinforced his powers by its adoption. It appears from a letter of Leibnitz to him, of October 1, 1693, that he was just then, eighteen months before his death, "beginning to find the convenience" of the infinitesimal mode of calculation, and had gone so far as to express publicly his approbation.

The most interesting part of the correspondence now before us refers to Huygens's observations on Saturn. As early as November 1652, we find him making inquiries as to the best manner of preparing and polishing lenses. Assisted by his brother Constantine, he prosecuted the subject with a diligence for which he half apologized to his learned friends, and which produced unwelcome gaps in his communications with them. By the commencement, accordingly, of 1655, he was in possession of a telescope of 12 feet focal length, undoubtedly the best produced up to that date. It showed him, not only the phases of Venus and the satellites of Jupiter, but—March 25, 1655—"aliud quid memorabile," unseen by Fontana or Hevelius, namely a Saturnian moon, afterwards named Titan, the sixth counting outward from the planet, the first in order of terrestrial detection. He concealed and endeavoured to secure his discovery, after the fashion set by Galileo, in an anagram which was widely circulated, and expounded in the following year. The precaution was nevertheless insufficient to prevent a claim to priority being put forward. Dr. Wallis, the Savilian Professor of Geometry, prepared on behalf of his friends Wren and Neile, a storage-battery of fame in the shape of a counter-anagram, which—if Huygens's private notes are to be relied upon—he fraudulently interpreted as an announcement similar in purport to that imparted to him from the Hague. Some unexplained circumstance possibly underlies a transaction on the face of it highly discreditable to our countrymen. The pretensions of the English observers were at any rate quickly and quietly withdrawn, and Huygens was left in undisturbed enjoyment of the credit most justly due to him.

Shortly after his return from Paris, late in 1655, he constructed a telescope of 23 feet, magnifying one hundred times; and the comparison of the observations it afforded him with those of the previous year enabled him at once to penetrate the mystery of Saturn's enigmatical appendages. His hypothesis as to their nature, wrapt up in the customary logogryph, was appended to his little tract on the Saturnian satellite, with an accompanying prediction of the future changes of figure to be expected in the planet. Its verification, however, falls outside the limits of the publication we are at present concerned with. Nor does it include any mention of the novel sight disclosed to Huygens by his improved instrument in the constellation of Orion, where a certain "hiatus" in the firmament permitted (as he supposed) the pure, faint splendour of the empyrean to shine through on his amazed vision.

Huygens had an eminently sane and sagacious mind. His fortunate intuitions were numerous, and the investigations they suggested were singularly solid and complete. A great part of his work was thus fitted to be, and has actually become, the substructure of the modern scientific edifice. He was, however, less happy in the few cases in which, relaxing his habitual prudence, he gave the rein to speculation. His prevision that the measure of discovery in the solar system was filled by the disclosure of Titan, was belied with scarcely civil haste by Cassini's further detections hopelessly overthrowing the numerical balance between six primary and six secondary bodies. And the surmises which constituted the bulk of his "Cosmotheoros" were, for the most part, infelicitous. Yet he reprehended, as woven out of figments, the Cartesian theory of the origin of the universe, and concluded with the wise and memorable words:—"To me it would be much if we could understand how things actually are, which we are far enough from doing. How they were brought about, what they are, and how begun, I believe to be beyond the range of human ingenuity to discover, or even by conjectures to approach."

A. M. CLERKE.

NORWEGIAN GEOLOGY.

Bömmelöen og Karmöen med Omgivelser. Geologisk beskrevne af Dr. Hans Reusch. (Kristiania: Published by the Geological Survey of Norway, 1888.)

THE attention of geologists in all parts of the world has for some years been concentrated upon the crystalline schists, which have so long presented insuperable difficulties to those who would explore their origin. Little by little the darkness has been rising from these ancient foundation-stones of the earth's crust; and though a long time must probably still elapse before their history can be even approximately sketched, there can be no doubt that we are now at last on the right road of investigation. Fresh evidence is continually being obtained from the most widely-separated regions, and each additional body of facts goes to support the view that the schistose rocks are the records of gigantic terrestrial displacements, whereby portions of the crust have been pushed over each other, and so crushed and deformed as to acquire new internal rock-structures. Out of these mechanical movements, with their accompanying chemical transformations, a true theory of metamorphism will no doubt eventually be evolved. In the meantime it is too soon to generalize; what we need is a far larger mass of observations. The subject is a wide one, for it involves the labours of the field-geologist, the petrographer, the mineralogist, the chemist, and the physicist. And only by the united exertions of these fellow-workers can we hope for good progress and solid results.

The most recent contribution to the question of the origin of the crystalline schists has just appeared in the form of a handsome volume, by Dr. Hans Reusch, on the Bömmel and Karm Islands off the mouth of the Hardanger Fjord. It consists of a mass of detailed observations on the structure of the crystalline rocks of that part of the Scandinavian coast, and furnishes an admirable array of fresh data for the study of the problems of regional metamorphism. Dr. Reusch's previous researches on the compressed conglomerates and metamorphosed fossiliferous rocks of the same district were of the utmost value in the discussion of the question, and he now augments these by new details from the surrounding region.

Especially important are the numerous illustrations of the effects of pressure and stretching in the production of the well-known structures of the crystalline schists. The strangely deceptive resemblance to stratification resulting from these processes is exhibited in many examples. Excellent instances are likewise given of the production of foliation in dykes. Eruptive diabases and gabbros are shown to pass into dioritic rocks, and hornblendic schists and granite into various foliated compounds. More novel features of the essay are the careful studies of the deformation and foliation of what were unquestionably at one time ordinary sedimentary deposits—sandstones, conglomerates, and limestones. It is shown, for instance, that in a mass of still recognizable conglomerate the planes of stratification are cut across, almost at right angles, by those of foliation, while the lines that mark the direction of stretching or deformation slant upwards across the latter.

Dr. Reusch brings forward some remarkable observations regarding the connection between conglomerates and granitic rocks. He thinks that in some places what is now granite has resulted from the metamorphism of what was originally a breccia or conglomerate composed of fragments of granite, gneiss, quartzite, and quartz. The quartzite and quartz, being less liable to change, remain still visible, while the granite and gneiss have passed into common granite. In another locality he finds what he believes to be evidence of the passage of a conglomerate into augen-gneiss. Without in any way calling in question the accuracy of his observations, a geologist who has had much experience among the crystalline schists in districts where great thrust-planes and other proofs of powerful displacements prevail, will recall examples of breccias that might at first be taken to be sedimentary masses, but which have eventually proved to be portions of rocks crushed during the disturbances that produced the schistose structure. Coarse pegmatites, for example, may be traced through various stages of comminution, until they pass at length, along the plane of movement, into finely fissile rocks, that in some cases might be mistaken for shales, in others for eruptive rocks with the most exquisitely developed flow-structure. The "eyes" in some augen-gneisses are almost certainly fragments resulting from the crushing of largely crystalline rocks, such as coarse pegmatites.

Dr. Reusch shows that in Scandinavia, as in the north-west and north of the British Isles, the axes of the great terrestrial plications run, on the whole, from north-east to south-west, and that as they have involved Upper Silurian strata in their folds, the movements must be of later date than some part, if not the whole, of the Upper Silurian period. His essay is most welcome as a valuable contribution to one of the most perplexing problems in geology. It once more shows him to be a careful and intrepid field-geologist, and, at the same time, a skilful worker with the microscope. This combination of qualifications fits him in a special manner for the researches to which he has devoted himself with so much ardour and success. His volume is copiously illustrated with figures in the text, and a selection of coloured geological maps. English geologists will also welcome in it a copious English summary of the contents. We may confidently predict that, before long, some of his drawings will be reproduced in the text-books as standard representations of the facts of regional metamorphism.

A. G.

TRAVELS IN ARABIA DESERTA.

Travels in Arabia Deserta. By C. M. Doughty. 2 Vols. (Cambridge: University Press, 1888.)

MR. DOUGHTY'S book takes us back to the age of the old travellers. His wanderings were in countries where not only no European had preceded him, but where he had to travel with his life continually in his hand. He travelled alone, and without any of the equipment which the modern explorer considers a necessity of existence, living with the Beduin of the desert, and sharing with them their wretched subsistence. Even the style in which he writes is a style in which it is safe to say no Englishman has written for the last two hundred years, and while it attracts us by its quaintness it makes us not unfrequently wonder what is exactly the author's meaning. Indeed, were it not for the very excellent index, it would often be almost impossible to find one's way through the labyrinth of Mr. Doughty's sentences or to ascertain the exact chronology of his route.

Mr. Doughty seems to have been born under an evil star. While he possesses most of the requisites of a successful traveller—a love of adventure, an insatiable curiosity, indomitable patience, and extraordinary powers of endurance—he lacks, on the other hand, just those qualities which would have smoothed his journey and made his life more comfortable. He is a man, by his own confession, of blunt and plain speech, improvident and forgetful, with an old-world belief in the falsity of Mohammedanism and the Koran, and the iniquity of countenancing them even by a politic word. His explorations took place at the time of the war between Turkey and Russia, when the fanaticism of the Mohammedans of Arabia was excited to the utmost, and he had to leave Damascus at the outset of his journey without any letters or help from the British Consul. The latter, indeed, declared that "he had as much regard of" him, would he "take such dangerous ways, as of his old hat." It is no wonder that Mr. Doughty complains of conduct which caused him "many times come nigh to be foully murdered."

His explorations were conducted in Central Arabia, a country which is less known than Central Africa. He accompanied the Mecca pilgrims as far as "the kella" or fort of Medain, where he lived with the Turkish garrison, visiting from time to time the ruins of Medain Salihh, and taking squeezes of the Nabathean inscriptions there. After some months he joined the nomad Beduin, and wandered with them in various directions, visiting the lava crags on the west and Teyma on the north-east. Eventually he made his way to Háyil in the Nejd—a centre of Wahabi fanaticism—where a sort of settled government was established under Ibn Rashîd. From Nejd he was forwarded, along with some Beduin, to Kheybar, not far to the north of Medineh, where he found himself once more within what was nominally Turkish territory, and was arrested as a spy. Released after a while, he was sent back again, for reasons which are never explained, to Háyil, and here his troubles began. The people of the place would not receive the Christian stranger a second time; his Beduin escort were afraid of bringing him back to Kheybar, and after a series of misadventures he was finally deserted near Aneyza, a town considerably to the south of Háyil. The governor and leading merchants of Aneyza fortunately befriended him, and he at last found his way to Taif and Jedda, though not without being first stripped of the little that still belonged to him, and narrowly escaping with his life.

Mr. Doughty was a careful observer, and he has not only made important additions to our geographical knowledge of Arabia, but also to our geological knowledge of it. The inscriptions he obtained at Medain Salihh and elsewhere have been published by the French Government, and important inferences have been drawn from them. They prove not only that a powerful and civilized State existed in this part of Arabia far on into the Christian era—a fact which was already known—but that this State was Nabathean in its language and character. M. Berger has come to the conclusion that before the rise of Mohammedanism the Arabic of the Koran was the language of Mecca only and the surrounding district, the Nabathean with its Aramaic affinities prevailing in the northern part of Arabia, and the Himyaritic in the south. It seems clear, at all events, that the Nabathean and Himyaritic civilizations once adjoined one another, and that their overthrow marked the triumph of the Beduin children of Ishmael. Since Mr. Doughty's travels, Prof. Euting and M. Huber (who was afterwards murdered by the Hharb Arabs) have visited Medain Salihh and Teyma, and carried away with them a large number of valuable inscriptions. One of these, on a stêlê discovered at Teyma, is now in Paris.

It is interesting to find Mr. Doughty confirming the statement that the final *n* of classical Arabic is still pronounced in the Nejd. His remarks on the diseases prevalent among the natives are also curious, though it is difficult to believe that the ophthalmia from which he had himself suffered is due to drinking cold water before going to bed. Everyone, however, who has had much experience of the Beduin will agree with the character he gives of them. The Egyptians have a proverb: "He who shows a Beduin the way to his door will have long sorrow"; and the traveller is unfortunate who is compelled to intrust himself to their tender mercies.

OUR BOOK SHELF.

Charts showing the Mean Barometrical Pressure over the Atlantic, Indian, and Pacific Oceans. (London: Published by the Authority of the Meteorological Council, 1888.)

THESE charts are issued in the form of an atlas, and deal in a very complete manner with the barometer means and range of all oceans. The months for which separate charts are given are February, May, August, and November, which have been selected to represent the mean values for winter, spring, summer, and autumn respectively in either hemisphere. In addition to the large charts, which give the material in considerable detail, there are four index charts, on a smaller scale, which exhibit for the same months the isobars, or lines of equal pressure, over the entire globe. These are followed by four charts, on the same scale, showing the range of barometrical pressure. The observations have been derived from logs and documents deposited in the Meteorological Office; logs and remark-books of Her Majesty's ships, furnished by the Admiralty; published narratives of various voyages, and various published results of other nations; also observations at coast stations and islands obtained from all available sources. The number of observations obtained from the Meteorological Office logs for the several oceans are: the Atlantic Ocean, 339,300; the Indian Ocean, 162,000; the Pacific, 88,300.

The barometrical means are given in large figures for areas of 5° of latitude by 5° of longitude, and for the benefit of those who require the material in greater detail smaller figures are given to show the means for areas of 2° of latitude by 2° of longitude, the several means being obtained from the daily averages. The range to the nearest tenth of an inch for each 5° area is placed over the mean for that area, and the number of observations under it; so that the charts not only supply the navigator with all the detail he is likely to require, but afford opportunity of the values being combined by other compilers with material of a similar nature. The isobars are given for each tenth of an inch, and the free use which has been made of the barometrical values for the coast stations greatly enhances the degree of dependence of the several lines. To facilitate the use of the charts for the navigator, the observations are corrected for a constant altitude of 11 feet above the sea, and are reduced to 32° F., but are not corrected for gravity; a table is, however, given on the face of each chart to facilitate this correction.

The general charts which give the isobars of the globe show very conspicuously the prevalence of high-pressure areas in each ocean in each of the four seasons. Change is of course shown in the distribution of pressure, but there is the same tendency to the persistency of high reading. It is seen that these areas oscillate and alter somewhat in intensity with the season, but there are many characteristics in common. The northern Indian Ocean, which is much more surrounded by land, is, however, an exception, the high pressure being situated over the northern part of the ocean, in November and February, and decreasing southwards; whilst in May and August the pressure is lowest in the north and increases southwards, this change being intimately related to the monsoon winds. The charts of range show well the influence of season, the largest differences occurring in the winter months in each hemisphere. In February the range to the west of the British Islands is 2·0 inches, whereas in August it is only one-half as great. The effect of latitude on the amount of range is very evident, the values near the equator being very small. These charts, which have been compiled by Nav.-Lieut. Baillie, R.N., are considerably in advance of any previous work of a similar nature, and will materially aid in explaining the general circulation of the wind over the globe, barometric pressure and wind being so intimately co-related.

Commercial Mathematics. (London: Longmans, Green, and Co., 1888.)

THIS volume is the continuation of a series of books on commercial education, and specially adapted for candidates preparing for the Oxford and Cambridge Schools Examination Board. Arithmetic is first dealt with, the first chapter consisting of an account of the decimal system in France. Moneys, weights, and measures, of Germany, Italy, Spain, Portugal, and Russia, are next discussed, followed by numerous examples; and the first part concludes with a chapter on "Exchange." Algebra is the subject of Part II., which extends as far as quadratic equations, including involution and evolution, and a chapter on the methods of testing algebraical results. The examples are very numerous throughout, and the book ought to be much in demand by the above-mentioned students and others. The volume concludes with a list of results of the various examples.

A Wanderer's Notes. By W. Beatty-Kingston. In Two Vols. (London: Chapman and Hall, 1888.)

FOR about thirteen years Mr. Beatty-Kingston acted as a newspaper correspondent, and in this capacity he had to visit many centres of life on the Continent. In the present volumes he offers a selection from the innumerable pen-and-ink sketches taken during his "multifarious peregrinations." The work, we need scarcely say, has no strictly scientific interest; but it is fresh and amusing, and will no doubt give pleasure to many a reader who has never had an opportunity of seeing the places described in its lively pages. The author is particularly successful in the chapters devoted to Germany, where he seems to have had exceptional means of making himself acquainted with the characteristics of the various classes of the community.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The "Sky-coloured Clouds" again.

THESE clouds have reappeared. Last night was the first occasion I have noticed any very distinct display of them this year; but I first saw them on June 12, and again on the 14th; and I think I saw them on June 13 and 17, but was not sure. Previous to that, on May 15 and 16, the green sky, when the sun had set, was of unusual brightness, showing, as I thought, a tendency to the formation of these clouds. Each summer they appear to be growing fainter since they were first generally noticed in 1885.

This year's observations were made in Cornwall, with the exception of last night's, which was at Sunderland.

Sunderland, June 26. T. W. BACKHOUSE.

Earth Pillars in Miniature.

I HAVE taken two photographs of an interesting specimen I obtained from the cliffs here. The stone is composed of very fragile sand-rock containing fragments of flint. A large mass of this became detached from the higher part of the cliff, and some of the pieces chanced to fall on a ledge upon which dry sand was constantly pouring in windy weather. The action of this falling sand wore away all parts of the surface of the stone save those protected by the small embedded fragments of flint, and hence the formation of these miniature pillars.

Owing to the extreme incoherency of the substance, I unfortunately lost one of the most perfect pillars before the photograph was taken.

I conclude that the formation of these pillars was the work of a very few days—perhaps hours. On visiting the spot a few days later, all traces of sand-action had been obliterated by rain. An analogous case was that described by Mr. Blake ("Geol. Miscell. Tracts," 10) as occurring in the Pass of San Bernardino, California; the surface of the granite had been worn by blown sand, but the garnets therein stood out in relief upon long pedicles of feldspar, as a proof of their superior hardness. CECIL CARUS-WILSON.

Bournemouth, June 23.

Egg-masses on *Hydrobia ulvæ*.

CAN any of your readers give me information in regard to the eggs of the Gastropod *Hydrobia ulvæ*?

At a recent excursion of the Biological Society to Hilbre Island, while crossing the great stretch of wet sand which lies in the estuary of the Dee, it was noticed that the surface was covered in some places with vast numbers of *Hydrobia*. Some of these were brought back to the laboratory in their wet sand; and, on being put in a dish of sea-water, the mollusks were found next day to have crawled out of the sand, and I then noticed that nearly every specimen had several little rounded excrescences scattered over the surface of its shell. On examining these, it was found that each was a little mass of small sand grains, in the centre of which was a clear jelly containing several segmenting ova or young embryos. They were undoubtedly molluscan eggs, as I kept them alive until one or two had reached a veliger stage; but did they belong to the *Hydrobia* or to some other mollusk? No other mollusk was, however, noticed in any abundance in the neighbourhood. Has, then, the *Hydrobia* acquired the habit of laying its eggs upon its neighbours' shells, as being the only comparatively stable objects to be found in the fine shifting sands around it? Possibly the method of oviposition of *Hydrobia* is already known, but I have not come across any reference to it. W. A. HERDMAN.

Zoological Laboratory, University College, Liverpool, June 23.

Interpretation of the Differential Equation to a Conic.

MAY I ask, with reference to Mr. Asutosh Mukhopadhyay's geometrical interpretation of the above in NATURE of the 21st inst., how to draw a *curve* at *every* point of which the radius of curvature vanishes, or the curvature is infinite?

Is it not evident that the osculating conic of a conic is the conic itself, and the "aberrancy curve" therefore a *point*, the centre of the conic?

The "sought found," then, is the fact that a conic is a conic!

June 24. R. B. H.

The Nephridia of Earthworms.

THE last number of the *Quarterly Journal of Microscopical Science* has just come into my hands, containing a paper, by Mr. Beddard, on the nephridia of certain earthworms. In November of last year I read a paper, before the Royal Society of Victoria, on the anatomy of the large Gippsland earthworm, *Megascolides australis*. This, which reaches the length of 6 to 8 feet, is, I believe, the largest recorded earthworm, and its nephridial system is of great interest, corresponding closely in many points to that described by Mr. Beddard, in the above paper, as present in *Acanthodrilus multiporus* and *Perichæta aspergillum*. My drawings have been for some time in the lithographers' hands, but as it will still be one or two months before the full paper is published, I should be glad to draw attention to the, in some ways, still more interesting features of the nephridial system in *Megascolides australis*. The nephridia are very evident, and can be divided clearly into two sets.

(1) A great number of small vascular-looking little tufts lining the body-wall, save in the mid-dorsal and ventral lines, especially abundant in the segments containing the reproductive organs (segments 11–19). They have no internal opening.

(2) A series of much larger nephridia, one pair of which only is present in each of the segments in the middle and posterior regions of the body—that is, from about segment 120 to segment 500, or whatever may be the number of the last segment, which varies according to the worm's size. They are placed in the anterior part of each segment, whilst the smaller nephridia form a ring round the body-wall posteriorly. Each one has the usual ciliated funnel opening through the septum into the segment in front.

Throughout the body, where the smaller nephridia occur, there is a network of intra-cellular ducts lying immediately beneath the peritoneal epithelium in connection with the nephridia, and giving off an irregularly arranged series of branched ducts opening externally. Ventrally, also, there appears to be on either side, in the middle and posterior portions of the body, a longitudinal duct running from segment to segment within the most ventral pair of setæ: into this duct open, first, the larger nephridia, and, secondly, the most ventrally placed small nephridia of the same segment; the latter, again, are united with the network of ducts connected with the ring of smaller nephridia.

In the case of the latter there appear to be two somewhat differently formed sets of external openings. All over the body, except in the clitellar region, where there is a great glandular development in the body-wall, the duct leading to the exterior is intercellular, small, and composed of minute cubical cells; in the clitellar region, on the other hand, the duct, though similarly intercellular, is much swollen out, slightly coiled, and always provided with a distinct coiled blood-vessel running by its side: its lining cells form a flattened epithelium.

The external opening itself is formed of cells of the epidermis, so modified as to present very much the external appearance of a taste-bulb—that is, they form a sphere with the cells thicker in their middle parts, and the two ends attached to the poles of the sphere, the duct passing right up through the centre. This structure of the external opening is common to all the ducts in the body, but is more clearly made out in the case of those referred to.

The large size and ciliated funnels of the paired nephridia distinguish these clearly from the more numerous smaller ones, which are devoid of internal openings, and are without a doubt homologous with those of *Acanthodrilus* and *Perichæta*. At the same time it is important to note that histologically the network of ducts and the longitudinal duct, which are intimately connected with each other, are precisely similar in structure, and, *a priori*, might be expected to have a similar origin, *i.e.* to be derived from the same germinal layer.

Leaving out of consideration at present the question dealt with by Mr. Beddard and others as to the homology of the larval nephridia of Chætopods, and assuming the existence of a genetic relationship between the adult nephridial system of Platyhelminths and Chætopods, the following questions suggest themselves with regard to the various nephridial structures present in different forms:—

(1) Are the longitudinal ducts in *Lanice*, the embryo of *Lumbricus* and *Megascolides*, homologous with each other? Before this can be determined the development of each must be known.

(2) Granted, of which there can be little doubt, that the smaller nephridia of *Megascolides* are homologous with the nephridia of *Perichæta* and *Acanthodrilus*, are not the large nephridia of the former, which are completely wanting in both

of these, homologous with the nephridia of other worms, such as *Lumbricus*, to which they are at all events suspiciously similar in arrangement and structure?

(3) What is the relationship of the large to the smaller nephridia? Are they modifications of the latter, or independent later developments?

(4) In either case the Platyhelminth system must be more closely represented by the small nephridial bodies devoid of internal openings and provided with a network of ducts such as is found in *Perichæta*, *Acanthodrilus*, and *Megascolides*, than by the more specialized paired nephridia of such a form as *Lumbricus*.

Possibly the course of development as represented in living forms may be somewhat as follows:—

(1) A series of numerous nephridia present in each segment devoid of internal openings, and connected by a continuous network of ducts, as in *Perichæta*.

(2) The aggregation of these smaller nephridia into tufts in various parts, as in the posterior region of *Acanthodrilus*; the subsequent enlargement of certain of these nephridia and the acquirement by them of secondary internal openings. It is interesting to note in *Megascolides* that in the anterior part of the body, where the small nephridia are scattered over the whole body-wall of the segment, large nephridia are absent, whilst they are present in the posterior region, where the small nephridia are confined to a ring in the posterior part of the segment. In this case, as the nephridia become aggregated into tufts in the anterior part, the ducts connecting them with those in the posterior region of the segment next in front will become fewer, until when, as in *Megascolides*, only a single, modified, large nephridium remains on either side anteriorly, there will be simply one duct from segment to segment uniting with a network of ducts in the region where the small nephridia still persist.

It is interesting to note that the aggregation of the smaller nephridia, and on this supposition the modification of certain of them to form the larger ones, commences in the posterior region of the body.

In certain worms, such as *Acanthodrilus*, the connection of the network of ducts from segment to segment seems to have been lost, at any rate in the adult: aggregation of these in the neighbourhood of the setæ, and subsequent modification, would give rise to a certain number of nephridia in each segment without any longitudinal duct.

(3) The next stage is reached in such a form as *Lanice*, where the longitudinal duct persists, but all trace of the smaller nephridia is lost.

(4) The final stage is present in most earthworms where, in the adult, all traces of both small nephridia and longitudinal duct are lost, though the latter is present, as in *Lumbricus*, during development.

These lead to three conclusions, two of which are practically identical with those of Mr. Beddard:—

(1) That the smaller nephridia without internal openings, irregularly scattered, and with a network of ducts such as are seen in *Acanthodrilus*, *Perichæta*, and *Megascolides*, are homologous with the nephridial system of Platyhelminths.

(2) That the larger nephridia typical of most earthworms are secondary modifications of certain of the smaller ones subsequent to their aggregation into groups; the modified ones acquiring each an internal opening.

(3) That there is no homology between the longitudinal duct of *Lumbricus*, *Lanice*, *Megascolides*, &c., with that of the Platyhelminths, since it has only been developed in the above forms in connection with the larger nephridia and as a modification of the original network, and has thus had its origin within the Chætopod group. W. BALDWIN SPENCER.

Melbourne University, May 3.

Strange Rise of Wells in Rainless Season.

MY attention has been directed to a letter published by you a few weeks ago (May 31, p. 103) under the above heading. It would appear that there is something mysterious in the eyes of the author of the communication in question in the fact that the water in two wells at Fareham rose several feet in the month of March, as he states, "after a continuance of north-east wind, *without rain*, but with half a gale blowing"; so that it would appear that there was some connection between the north-easterly gale and the rise of the water.

In this, however, the author is entirely mistaken; the rise of water in the wells in question is nothing more than the ordinary seasonable rise due to percolation. For twelve years past I have been carrying on constant observations of the underground water-supplies in various parts of this country, and it is quite true, as mentioned by the writer of the letter, that ordinarily the water in wells rises in the winter and falls in the summer; but this is by no means an exceptional rule, for in the present season there have been two low waters, the last of which occurred in the southern counties on the 8th of March in the present year. After that date commenced a very wet period, and before the end of the month over $2\frac{1}{2}$ inches of rain had absolutely passed through the ground as measured by my percolation gauges. The water in a well on the Surrey hills, which had been falling up to March 8, rose before the end of the month over 30 feet, which rise was entirely due to the replenishment from rainfall. I may point out that there are many wells at the present time in which the water is still rising, while in others in the same districts the water is falling, for the simple reason that as a rule underground water follows the same law as water flowing in a river, and that the floods or high waters descend from the highest to the lowest districts, so that at present in wells situated in high positions the water is falling, while the crest of the wave of high water in the same watershed has not yet been reached in the lower levels of the district.

That the water in wells *does* fluctuate under certain conditions of the wind there is no doubt, as I have already drawn attention both to the fluctuations which take place in the water-levels of wells under barometric pressure and also in the volume of water discharged from the ground with a fall of the barometer. It should be noted that the rise of water in wells when due to barometric changes coincides with the fall of the barometer. Now a north-easterly wind as a rule is accompanied by a high barometer, and therefore is not likely to influence the rise of water in a well. During the month of March the rainfall was above the average, while there were comparatively few days with easterly winds, the only time when it could be termed a half-gale from the north-east occurring on the 19th of March, by which time the water in all the wells had made a considerable rise, due simply to ordinary percolation. Thus there is no mystery attaching to the rising of the water in these wells at Fareham. The rise simply took place from the replenishment of the springs, which this year occurred at a period somewhat different from ordinary years. BALDWIN LATHAM.

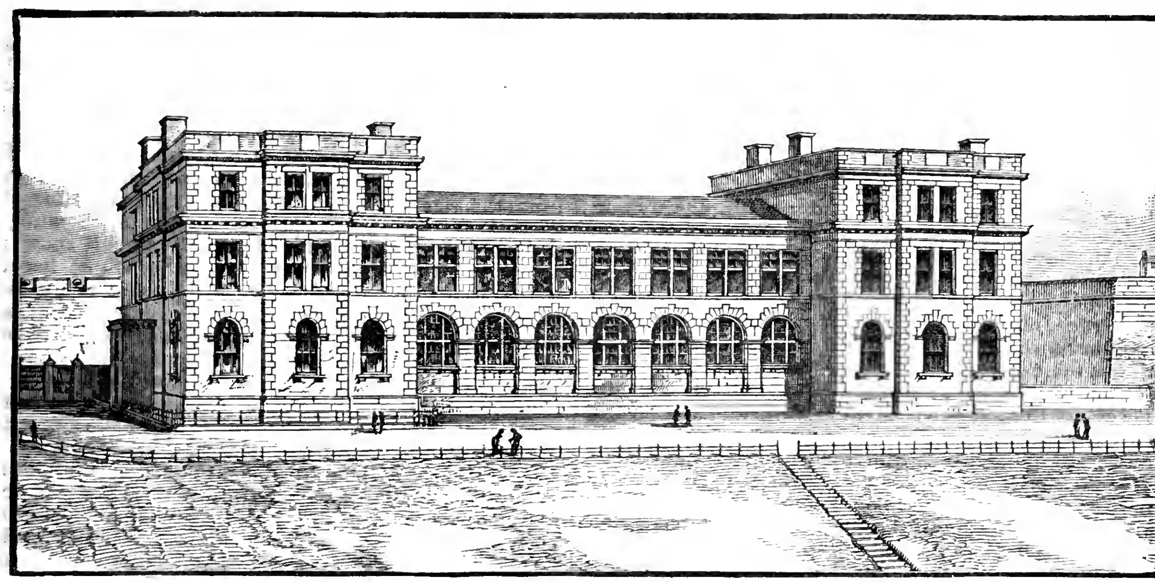
7 Westminster Chambers, Westminster, June 21.

THE OPENING OF THE MARINE BIOLOGICAL LABORATORY AT PLYMOUTH.

THE Laboratory at Plymouth, which is now ready for work, is remarkable as being the first institution in this country designed purely for scientific research which has been originated and firmly established by the efforts of scientific men appealing to the generosity and confidence of wealthy individuals and corporations who desire the progress of knowledge for practical ends and the general good of the community.

It may be said that the Marine Biological Association will begin its active career on and after Saturday next. On that day Prof. Flower will, on behalf of the Association, declare that the Laboratory at Plymouth, which is now complete, is open for the purposes of biological research. The opening of the Laboratory may be said to mark an epoch in English zoological science, just as the opening of the Stazione Zoologica at Naples, which is essentially a German undertaking, marked an epoch in German science. It is true that small sea-side laboratories have already been established in the United Kingdom—at Granton, St. Andrews, and Liverpool Bay; but none of them can compare with the present undertaking in size and importance, and none can offer such advantages to the investigator.

The present institution, it may be remembered, is historically the outcome of the International Fisheries Exhibition held in London in 1883. That Exhibition served partly as an amusement to Londoners, but it also performed a far more important service—it directed people's minds towards the importance of our fisheries, and made them in some slight degree acquainted with the conditions under which those fisheries are worked. At the close of the Exhibition a large balance was left in the hands of its promoters, and it was hoped by many leading men of science that the money thus obtained would be utilized, in part at least, for the purpose of encouraging investigations upon the habits and economy of food-fishes. But the money was appropriated to other purposes, excellent in themselves, though useless as a means of promoting the welfare of the fishing industry. Prof. Lankester, however, nothing daunted by this want of success in obtaining funds from the surplus of the Fisheries Exhibition, and feeling that it was time to strike whilst people's minds were awakened to the importance of our fisheries and to the lack of scientific knowledge concerning them, determined to found an Association for the purpose of encouraging the study of the marine fauna of the British coasts, and with the consent and co-operation of the officers of the Royal Society called a meeting for this purpose in the rooms of the Society on March 31, 1884. The meeting was eminently successful. The Duke of Argyll proposed a resolution to found the Marine Biological Association of the United Kingdom, and was supported by the most eminent biologists in the country. An appeal was made for subscriptions in aid of the Association's projects, and was soon liberally responded to. His Royal Highness the Prince of Wales graciously consented to be patron of the Association, and gave liberally to its funds; the scientific Societies, the City Companies, the Universities, and finally Her Majesty's Government, joined the list of subscribers; and in a short time the Association was in a position to undertake the building of a laboratory. After some debate as to the most suitable locality for a laboratory, Plymouth was selected, partly because it is a large and important fishing port, partly because the richness of the marine fauna of the Sound and neighbouring shores was extolled by such eminent authorities as the late Dr. Gwyn Jeffreys, Mr. C. Spence Bate, and Prof. Charles Stewart. The Association was fortunate in securing a magnificent site for the Laboratory from the War Office. For this site, than which a better could not be found, the Association is greatly indebted to the Earl of Morley,



South Front of the Laboratory of the Marine Biological Association, on the Citadel Hill, Plymouth.

then Under-Secretary of State for War, and to Sir Andrew Clarke, Inspector-General of Fortifications. The site granted is that part of the fosse of the Citadel lying to the south of the portion of the Citadel wall known as King Charles's Curtain; it has a frontage towards the sea of 265 feet, and extends some 240 feet southwards of the Citadel.

The Laboratory which has been erected upon this site is admirably adapted to the purposes of the Association. It is, indeed, more than a laboratory, it is also an aquarium, whose tanks are extensive and fitted with every improvement that modern science can suggest. The total cost of building, machinery, and fittings, including all fees, has been about £12,500. The structure comprises a central portion with a wing at either end. The east wing is almost wholly taken up by the residence of the Director, and needs no further comment. The west wing has on the ground floor the caretaker's rooms, and a receiving-room into which the results of the day's fishing will be brought for examination. On the first floor are chemical and physiological laboratories, and on the second floor a library, a work-room, and lavatory. The main part of the building contains on the ground floor the aquarium or tank-room, and on the first floor the large laboratory. The tank-room is fitted with slate and glass tanks, of which one on the northern side is a noble window tank, 30 feet in length, 9 feet in breadth, and 5 feet deep. There are three large window tanks on the north side, nine smaller window tanks on the south side, and a series of five table tanks in the middle of the room. The tanks are supplied with salt water from two reservoirs, capable of holding 50,000 gallons each. From these the salt water is led by means of pumps through vulcanite pipes into the tanks; the openings of the pipes are placed rather more than a foot above the level of the water in the tanks, and are provided with nozzles through which the water is forced at high pressure, so as to form jets descending deep into the tank and carrying with them a quantity of atmospheric air. Circulation has been established in the tanks for the last fortnight, and there is every reason to be satisfied with the arrangements for aërating the water. The jets carrying down the air deep into the water of the tank cause it to be filled with minute bubbles so as to resemble champagne, and all the animals that have hitherto been placed in the tanks are thriving in a remarkable manner, which is the more surprising as new tanks are generally supposed to be highly injurious to organisms introduced into them at an early a date. It would be too much to expect that tanks which have been so lately put up should be fully stocked within a fortnight, nevertheless they will present to the visitors on Saturday next a sufficiently interesting collection of local marine forms. For the rest the tank-room is a plain room, without any attempt at ornamentation. It is felt that the scientific nature of the institution must be kept in the foreground, and therefore nothing has been done to make the aquarium a place of popular amusement.

The main laboratory is at present fitted with seven compartments, each to contain a single naturalist, along its north side. When the necessity arises, similar compartments will be placed along the south side. In the centre of the room is a series of slate and glass tanks supplied with salt water from the circulating pumps. Beneath these a convenient shelf has been arranged, so that naturalists will be able to arrange for themselves any temporary apparatus that they may devise on as small a scale as is desired. All the arrangements for laboratory work will be completed at the end of the week, and the only thing now required is a company of ardent naturalists ready to undertake the work that lies to hand.

The material for work and for stocking the tanks is obtained from the Sound and the sea outside the breakwater by means of the trawl, dredge, and tow-net. In general a small shrimp-trawl is used in preference to a dredge, as it is much wider and equally effective in collecting the animals that live at the bottom. Hitherto the Association has been content to hire fishing-boats for dredging and trawling. Most of the work has been done in a small hook-and-line boat, the *Quickstep*, of about 6 tons burden, and on special occasions the trawler *Lola*, of 50 tons burden, has been hired. But this method of hiring is too expensive to be continued; the Association will soon have to purchase boats, and probably will find it necessary to acquire a steam-boat. Without a steam-boat the station is at the mercy of the weather. If it is a dead calm—and calms are frequent in summer along the south coast—no dredging or surface netting can be done, a cruel fate when one knows that the pelagic surface fauna swarms thickest on bright calm days. Or if it is wished to explore a certain region on a certain day, if the winds prove contrary more than half the day is lost in beating up to the station; in any case one may generally expect to have a contrary wind on either the outward or the homeward journey. Such losses of time and material are most prejudicial to an institution like the Marine Biological Association. A steam-launch has been found necessary at all other marine stations. Dr. Dohrn has two, the *Johannes Müller* and the *Francis Balfour*, at Naples; and the Granton Station is well provided for by the steam-yacht *Medusa*. But the funds of the Association have been well nigh exhausted in the building of the Laboratory. If a steam-launch is found requisite, it will be necessary to make another appeal to its friends, which, let it be hoped, will be as heartily responded to as the first appeal for funds for building the Laboratory.

It was stated in the early part of this article that the Association would begin its active existence on the 30th. It would have been more proper to say its active public existence, for its staff has been active for some time past. Under the guidance of Mr. W. Heape, the late Superintendent, a careful though necessarily incomplete exploration of the Sound has been made, and numbers of animals have been identified, preserved, and put aside for future reference. Mr. Heape has also drawn up a complete list of the fauna and flora of the Sound, as recorded up to the present date, and a very formidable list it is.[1] Botanists will note that there are more than 250 species of marine Algæ recorded from the neighbourhood, and some of them are extremely rare. Zoologists will see that there is an unlimited field in certain groups, particularly in the Crustacea and the Mollusca, but that some of the most interesting forms, the "pets of the laboratory," such as Amphioxus and Balanoglossus, are absent. But to say that they are absent means only that other less familiar forms are present, and that these old favourites have not been recorded. A good authority states that Amphioxus can be found in the immediate neighbourhood, whilst it is confidently expected that both Balanoglossus and Amphioxus can be introduced from the Channel Isles, and kept alive in the tanks. The zoologist need not fear that he will be hindered by the poverty of the fauna; there is material enough and to spare. The remarkable Hydroid, *Myriothela*, occurs at low-tide mark in considerable quantities. The interesting Actiniæ, *Edwardsia* and *Peachia*, are to be found. Appendiculariæ and Sagittæ are taken in hundreds in the tow-net. *Antedon rosaceus* is abundant a quarter of a mile from the Laboratory, and magnificent specimens of Pinna will attract the interest of the malacologist.

Such an institution as that at Plymouth challenges comparison with Dr. Dohrn's famous zoological station at Naples. But there is this remarkable difference between them. The Naples Station was founded for purely scientific objects: it does not profess to undertake investigations for the benefit of economic interests. The Marine Biological Association receives an annual grant from the Treasury, on the express understanding that it shall conduct researches upon questions relating to the life-history and habits of food-fishes. It must not be supposed that this work is not scientific because it has a practical object in view. Science is not only the art of thinking correctly, but of observing and recording correctly, and correct observations and records of the life-history of our food-fishes are just what are wanted at the present time. The work of Mr. J. T. Cunningham, Naturalist of the Association, is an admirable example of scientific method as applied to a practical investigation. Mr. Cunningham has been working for several months at the development of fishes, with the view of obtaining and artificially fertilizing their ova and rearing their young in captivity. His results are necessarily incomplete, as he has been working in a half-finished laboratory, without gas or water, and under unfavourable conditions as regards boats and men. But he has succeeded in tracing out the life-history of the "merry sole" (*Pleuronectes microcephalus*), and has acquainted himself with such important facts concerning the development of the common sole, that he confidently expects to be able to hatch out the young next season, his experiments this year having failed only for want of the proper apparatus. He has also recorded the interesting fact that the herring spawns continuously from January to June in the Channel, and appears to have no definite breeding-season as it has in northern waters; and has discovered important facts relative to the breeding of the mackerel, conger, and pilchard, which will be made public as soon as his researches are complete. He has now stocked one of the large tanks in the aquarium with conger, and hopes in a short time to give a final opinion on the obscure question of the breeding of this fish. Not less interesting than Mr. Cunningham's researches are those of Mr. Weldon on the breeding of the common lobster, and the rock-lobster or craw-fish (*Palinurus*). Another of the tanks in the aquarium is occupied by the "berried" females of these forms, whose bright colours and active movements are as attractive to the casual spectator as their study is interesting to the zoologist and fisherman. So much has been

[1] Mr. Heape's list will be published in the forthcoming number (No. II.) of the Journal of the Marine Biological Association.

done already by Messrs. Cunningham and Weldon under the most unfavourable conditions that it cannot but be anticipated that when a number of investigators are working under favourable conditions on different groups, but with a common object in view, results of the greatest scientific and practical importance will accrue.

The ceremony on Saturday will be interesting and important. Many of the leading biologists in England will be present, but unfortunately the eminent President of the Association, Prof. Huxley, will be absent on account of ill-health, and so, unfortunately, will Prof. Moseley, one of its most ardent and generous supporters. The Fishmongers' Company have added to their munificent patronage of the institution by undertaking the entertainment of the numerous guests who have been invited to the ceremony; and the Association will be launched on its career of usefulness in a manner worthy of its aspirations, and satisfactory in the highest degree to its energetic promoters. G. C. B.

PERSONAL IDENTIFICATION AND DESCRIPTION.[1]

II.

PERSONAL characteristics exist in much more minute particulars than those described in the last article. Leaving aside microscopic peculiarities which are of unknown multitudes, such as might be studied in the 800,000,000 specimens cut by a microtome, say of one two-thousandth part of an inch in thickness, and one tenth of an inch each way in area, out of the 4000 cubic inches or so of the flesh, fat, and bone of a single average human body, there are many that are visible with or without the aid of a lens.

The markings in the iris of the eye are of the above kind; they have been never adequately studied except by the makers of artificial eyes, who recognize thousands of varieties of them. These markings well deserve being photographed from life on an enlarged scale. I shall not dwell now upon these, nor on such peculiarities as those of hand-writing, nor on the bifurcations and interlacements of the superficial veins, nor on the shape and convolutions of the ear. These all admit of brief approximate description by the method explained in the last article—namely, by reference to the number in a standard collection of the specimen that shall not differ from it by more than a specified number of units of unlikeness. I fully explained what a unit of unlikeness was, and certain mechanical means by which a given set of measures could be compared with great ease and by a single movement with every set simultaneously, in a large standard collection of sets of measures.

Perhaps the most beautiful and characteristic of all superficial marks are the small furrows with the intervening ridges and their pores that are disposed in a singularly complex yet even order on the under surfaces of the hands and the feet. I do not now speak of the large wrinkles in which chiromantists delight, and which may be compared to the creases in an old coat or to the deep folds in the hide of a rhinoceros, but of the fine lines of which the buttered fingers of children are apt to stamp impressions on the margins of the books they handle, that leave little to be desired on the score of distinctness. These lines are found to take their origin from various centres, one of which lies in the under surface of each finger-tip. They proceed from their several centres in spirals and whorls, and distribute themselves in beautiful patterns over the whole palmar surface. A corresponding system covers the soles of the feet. The same lines appear with little modification in the hands and feet of monkeys. They appear to have been carefully studied for the first time by Purkinje in 1822; since then they have attracted the notice of many writers and physiologists, the fullest and latest of whom is Kollman, who has published a pamphlet upon them, "Tastapparat der Hand" (Leipzig, 1883), in which their physiological significance is fully discussed. Into that part of the subject I am not going to enter here. It has occurred independently to many persons to propose finger-marks as a means of identification. In the last century, Bewick in one of the vignettes in the "History of Birds" gave a woodcut of his own thumb-mark, which is the first clear impression that I know of. Some of the latest specimens that I have seen are by Mr. Gilbert Thomson, an officer of the American Geological Survey, who, being in Arizona, and having to make his orders for payment on a camp suttler, hit upon the expedient of using his own thumb-mark to serve the same purpose as the elaborate scroll engraved on blank cheques—namely, to make the alteration of figures written on it, impossible without detection. I possess copies of two of his cheques. A San Francisco photographer, Mr. Tabor, made enlarged photographs of the finger-marks of Chinese, and his proposal seems to have been seriously considered as a means of identifying Chinese immigrants. I may say that I can obtain no verification of a common statement that the method is in actual use in the prisons of China. The thumb-mark has been used there as elsewhere in attestation of deeds, much as a man might make an impression with a common seal, not his own, and say, "This is my act and deed"; but I cannot hear of any elaborate system of finger-marks having ever been employed in China for the identification of prisoners. It was, however, largely used in India, by Sir William Herschel, twenty-eight years ago, when he was an officer of the Bengal Civil Service. He found it to be most successful in preventing personation, and in putting an end to disputes about the authenticity of deeds. He described his method fully in NATURE, in 1880 (vol. xxiii. p. 76), which should be referred to by the reader; also a paper by Mr. Faulds in the next volume. I may also refer to articles in the American journal *Science*, 1886 (vol. viii. pp. 166 and 212).

The question arises whether these finger-marks remain unaltered throughout the life of the same person. In reply to this, I am enabled to submit a most interesting piece of evidence, which thus far is unique, through the kindness of Sir Wm. Herschel. It consists of the imprints of the two first fingers of his own hand, made in 1860 and in 1888 respectively; that is, at periods separated by an interval of twenty-eight years. I have also two intermediate imprints, made by him in 1874 and in 1883 respectively. The imprints of 1860 and 1888 have now been photographed on an enlarged scale, direct upon the engraver's block, whence Figs. 9 and 11 are cut; these woodcuts may therefore be relied on as very correct representations. Fig. 10 contains the portion of Fig. 9 to which I am about to draw attention. On first examining these and other finger-marks, the eye wanders and becomes confused, not knowing where to fix itself; the points shown in Fig. 10 are those it should select. They are those at which each new furrow makes its first appearance. The furrows may originate in two principal ways, which are not always clearly distinguishable: (1) the new furrow may arise in the middle of a ridge; (2) a single furrow may bifurcate and form a letter **Y**. The distinction between (1) and (2) is not greatly to be trusted, because one of the sides of the ridge in case (1) may become worn, or be narrow and low, and not always leave an imprint, thus converting it into case (2); conversely case (2) may be changed into (1). The position of the origin of the new furrow is, however, none the less defined. I have noted the furrow-heads and bifurcations of furrows in Fig. 9, and shown them separately in Fig. 10. The reader will be able

[1] The substance of a Lecture given by Francis Galton, F.R.S., at the Royal Institution on Friday evening, May 25, 1888. Continued from p. 177.

to identify these positions with the aid of a pair of compasses, and he will find that they persist unchanged in Fig. 11, though there is occasional uncertainty between cases (1) and (2). Also there is a little confusion in the middle of the small triangular space that separates two distinct systems of furrows, much as eddies separate the stream

Fig. 9.—Enlarged impressions of the fore and middle finger tips of the right hand of Sir William Herschel, made in the year 1860.

Fig. 10.—Positions of furrow-heads and bifurcations of furrows, in Fig. 9.

lines of adjacent currents converging from opposite directions. A careful comparison of Figs. 9 and 11 is a most instructive study of the effects of age. There is an obvious amount of wearing and of coarseness in the latter, but the main features in both are the same. I happen to possess a very convenient little apparatus for recording the positions of furrow-heads. It is a slight and small, but well-made wooden pentagraph, multiplying five-fold, in which a very low-power microscope, *with coarse cross-wires*, forms the axis of the short limb, and a pencil-holder forms the axis of the long limb. I contrived it for quite another use—namely, the measurement of the length of wings of moths in some rather extensive experiments that are now being made for me in pedigree moth-breeding. It has proved very serviceable in this inquiry also, and was much used in measuring the profiles spoken of in the last article. Without some moderate magnifying power, the finger-marks cannot be properly studied. It is a convenient plan, in default of better methods, to prick holes with a needle through the furrow-heads into a separate piece of paper, where they can be studied without risk of confusing the eye. There are peculiarities often found in furrows that do not appear in these particular specimens, to which I will not further refer. In Fig. 10 the form of the origin of the spirals is just indicated. These forms are various; they may be in single or in multiple lines, and the earlier turns may form long loops or be nearly circular. My own ten fingers show at least four distinct varieties.

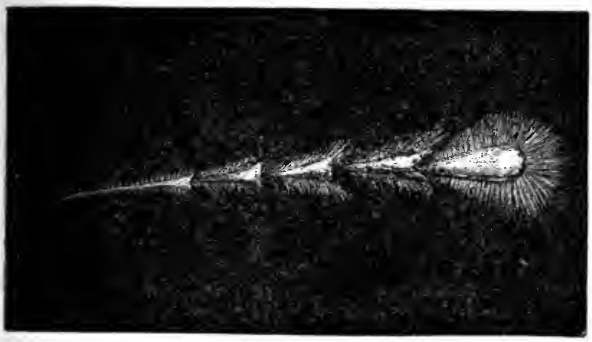
Notwithstanding the experience of others to the contrary, I find it not easy to make clear and perfect impressions of the fingers. The proper plan seems to be to cover a flat surface, like that of a piece of glass or zinc, with a thin and even coat of paint, whether it be printers' ink or Indian ink rubbed into a thick paste, and to press the finger lightly upon it so that the ridges only shall become inked, then the inked fingers are pressed on smooth and slightly damped paper. If a plate of glass be smoked over a paraffin lamp, a beautiful negative impression may be made on it by the finger, which will show well as a lantern transparency. The blackened finger may afterwards be made to leave a positive impression on a piece of paper, that requires to be varnished if it is to be rendered permanent. All this is rather dirty work, but people do not seem to object to it; rivalry and the hope of making continually better impressions carries them on. It is troublesome to make plaster casts; modelling-clay has been proposed; hard wax, such as dentists use, acts fairly well; sealing-wax is excellent if the heat can be tolerated; I have some good impressions in it. For the mere study of the marks, no plan is better than that of rubbing a little thick paste of chalk ("prepared chalk") and water or sized water upon the finger. The chalk lies in the furrows and defines them. They could then be excellently photographed on an enlarged scale. My own photographic apparatus is not at hand, or I should have experimented in this. When notes of the furrow-heads and of the initial shape of the spiral have been made, the measurements would admit of comparison with those in catalogued sets, by means of a numerical arrangement, or even by the mechanical selector described in the last article. If a cleanly and simple way could be discovered of taking durable impressions of the finger tips, there would be little doubt of its being serviceable in more than one way.

In concluding my remarks, I should say that one of the inducements to making these inquiries into personal identification has been to discover independent features suitable for hereditary investigation. It has long been my hope, though utterly without direct experimental corroboration thus far, that if a considerable number of variable and independent features could be catalogued, it might be possible to trace kinship with considerable certainty. It does not at all follow because a man inherits his main features from some one ancestor, that he may not also inherit a large number of minor and commonly overlooked features from many ancestors. Therefore it is not improbable, and worth taking pains to inquire whether each person may not carry visibly about his body undeniable evidence of his parentage and near kinships.

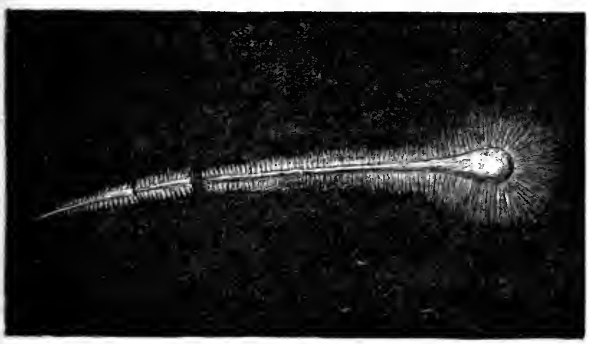
A MAGNIFICENT METEOR.

WE have received from Mr. C. Weatherall Baker (who writes from Penang) the following notes on a magnificent meteor seen from the s.s. *Prometheus* in longitude 62° E., latitude 10° 20′ N., at 10 40 p.m. on Friday, April 6, 1888:—

"It rose from the north by west horizon, and, passing behind a small cloud, travelled in a south by east direction, being at one period of its transit immediately above the ship. Sketch A represents the meteor when in that position. It traversed the whole arc of 180°, and was visible from first to last with the exception of the time when it was behind the small cloud before mentioned, the transit occupying about 30 seconds. When directly above the ship, the head appeared as near as possible the size of the moon when at its height, and the tail streamed out as in the sketch, to a length of about 15 diameters of the head. It was a brilliant white, and threw shadows on the deck as dense as those caused by the moon at the full. Sketch B represents the meteor as it appeared a few degrees above the horizon on its upward course, and on reaching the same distance above the south by east horizon it was simply a dull red ball with no tail whatever. Captain J. K. Webster, of the s.s. *Prometheus*, who has had many years' experience in most parts of the world, tells me that he has never seen a meteor in any way equalling this one for size or brilliancy."



A.—View as seen directly over ship at 10.40 p.m.



B.—View as seen shortly after appearing.

NOTES.

THE Council of the Royal Meteorological Society have issued a circular requesting that photographs of lightning may be sent to them. In response to a similar appeal last year, about sixty photographs of lightning-flashes were received from various parts of Europe and America. The Council remind photographers, amateur and professional, that the photography of lightning does not present any particular difficulties. "If a rapid plate, and an ordinary rapid lens with full aperture, be left uncovered for a short time at night during a thunderstorm, flashes of lightning will, after development, be found in some cases to have impressed themselves upon the plate. The only difficulty is the uncertainty whether any particular flash will happen to have been in the field of view. A rapid single lens is much more suitable than a rapid doublet; and it is believed that films on paper would effectually prevent reflection from the back. The focus should be that for a distant object; and, if possible, some point of landscape should be included to give the position of the horizon. If the latter is impossible, then the top of the picture should be distinctly marked. Any additional information as to the time, direction in which the camera was pointed, and the state of the weather, would be very desirable."

THE Kew Bulletin for June contains, besides an account of the manufacture of quinine in India, papers on "Job's Tears" (the round, shining fruits of a grass widely distributed in tropical countries, and used by the Karens for the decoration of clothing); on China grass or Ramie, the fibre of which, if it could be extracted and cleaned at a cheap rate, would have great economic value; and on a new botanical station at Lagos, which promises to exercise a very favourable influence on the industrial development of the West African colonies.

SOME time ago the Agassiz Association appointed a Committee to arrange for a seaside meeting during the present summer. This Committee, according to *Science*, proposes that the meeting shall be known as the "Agassiz Seaside Assembly." Its membership is to consist of such persons as shall send their names to the secretary before the opening of the assembly, or such as shall be elected members according to by-laws adopted afterwards. It is intended that the organization shall be made permanent. A six-days' session will be held this year, at Asbury Park, N.J., provided suitable accommodations can be secured at that place in the month of August. The subjects to be discussed this year will be principally botany and entomology, under the direction of such practical specialists as can be secured. The work is to include several field-day excursions with experienced guides.

THE heat in India lately has been unprecedented, in consequence of the delay of the monsoon. On June 24, when the Calcutta Correspondent of the *Times* despatched a telegram on the subject, the temperature was the highest that had ever been registered. Professional business was almost entirely suspended, and trading operations were greatly hampered. Many persons had suffered from heat-apoplexy and sunstroke, some cases having terminated fatally.

A *conversazione* was given yesterday evening by the President and Fellows of the Royal College of Physicians, at the College. The President of the Society of Telegraph-Engineers and Electricians, and Mrs. Graves, have issued invitations for a *conversazione* in the galleries of the Royal Institute of Painters in Water Colours on Tuesday, July 10.

A REMARKABLE new series of compounds of silicon tetrafluoride with organic derivatives of ammonia have been prepared by Messrs. Comey and Loring Jackson, of Harvard. Many years ago, Gay Lussac and Thénard discovered that silicon tetrafluoride formed with gaseous ammonia a singular compound, $2NH_3.SiF_4$; this substance, which is comparatively stable in air and distinctly crystalline, is decomposed by water with formation of ammonium fluoride and silicofluoride and deposition of silicic acid. The American chemists now show that a very large number of substituted ammonias form similar compounds, and give an interesting description of the methods by which they have isolated the most important members of the series. Aniline forms two such compounds, the most stable being represented by the formula $3C_6H_5NH_2 . 2SiF_4$, and the other $2C_6H_5NH_2 . SiF_4$, corresponding to the well-known compound with ammonia itself. The first was obtained by passing gaseous tetrafluoride of silicon over aniline, the gas delivery tube not quite touching the surface of the aniline so as to avoid the stoppage of the passage by the solid product. The combination is so rapid that practically all the fluoride is absorbed, considerable heat being evolved during the process; and, which is very satisfactory, the reaction is one of the few quantitative ones, the whole of the aniline being eventually converted into a loose white crystalline solid, which sublimes about 200° C. without fusion. This new substance is further remarkable by being insoluble in the usual organic solvents, alcohol alone slowly acting upon it with decomposition. Brought in contact with water it is at once decomposed with deposition of silicic acid; the solution, on evaporation, yielding beautiful pearly tabular crystals of aniline fluosilicate, aniline fluoride remaining dissolved. When aniline vapour was conducted into a receiver filled with silicon tetrafluoride the second compound was formed as a white powder, decomposing when warmed or when treated with water and even spontaneously on keeping. From the fact that the products of spontaneous decomposition are the first compound and free aniline, it is very probable that the true formula is $4C_6H_5NH_2 . 2SiF_4$, double the empirical formula; and it is evidently more than a mere coincidence that the values obtained by Mixter for the vapour density of the ammonia compound also point to the fact that its real composition is $4NH_3 . 2SiF_4$.

A SEVERE shock of earthquake was felt in the Hernö, an island in the Baltic, on June 7, at 7.24 a.m. Houses shook, and furniture moved. The shock went in a direction north-north-west. At the Lungö Lighthouse the shock was felt at 9.50, and was accompanied by a detonation like that of heavy artillery. Here the shock went in a direction north-east to south-west. The shock was also felt in the town of Hernösand.

A SPECIAL Committee, under Prof. Mushketoff, appointed to inquire into the causes of the earthquake which nearly destroyed Vyernyi, in Russian Turkistan, on June 9, 1887, has delivered its report to the Russian Geographical Society. The Committee, which consisted of four mining engineers and several topographers, began its work in August with a systematic exploration of the crevices in the buildings and the soil, both at Vyernyi and in the surrounding region as far as Lake Balkhash, Kulja, Lake Issyk-kul, and Tashkent. Detailed maps were made, and numerous photographs taken of the destroyed buildings. The chief shock of earthquake took place at 4h. 35m. a.m. on June 9; it destroyed nearly all the stone buildings of Vyernyi. It was followed at 4h. 45m. by another severe shock. Severe shocks continued for nearly half an hour, at intervals of one minute, and they were succeeded by feebler shocks which were felt throughout the day. Nearly 1500 stone houses were destroyed, while scarcely any harm was done to houses made of wood. Of a population of 30,000, no fewer than 332 persons were killed. The shocks continued almost every day throughout the months of June, July, and August; since September they have not been so frequent, but they go on still, and on March 4, 1888, there was a rather severe shock. The total number of shocks noticed (without instruments) reaches more than 200. It appears that the wave of earthquake had its origin in the south of Vyernyi, in the Alatau Mountains; and in the spur of mountains which separates the Kaskelen and the Berezovaya Rivers, the Expedition discovered at a height of from 5000 to 6000 feet a region where a dislocation of the rocks had taken place on an immense scale. The granitic and porphyritic rocks were dislocated and covered the slopes with masses of fresh *débris*. As to the softer deposits—clays and so on—which were still more softened by the very severe showers which preceded the earthquake, they were flowing and gliding like glaciers on the slopes of the mountains. One of these masses, on the Aksai River, has a volume of no less than 10,000,000 cubic metres. The centre of the earthquake was at a depth of from 5000 to 8000 metres, and its projection on the surface of the earth of the most severely affected regions covers a surface about twenty-three miles long and three miles wide on the northern slope of the Alatau. The earthquake spread with greater force towards the north than to the south; thus the region of the greatest destruction extends for about twenty-five miles northwards, and for only ten or thirteen miles southwards; but the whole region where the earthquake was felt has a length of nearly 1000 miles from south-west to north-east, and about 600 miles from south-east to north-west. As to its cause, it obviously must be searched for in the interior movements of the rocks—not in volcanic agencies. Regular seismological stations in Turkistan and the Caucasus will probably be the immediate outcome of the work of the Committee.

IN the *American Meteorological Journal* for May, Mr. Bôcher contributes an article on the labours of Dove, Redfield, and Espy, the greater part of whose work was included between the years 1830 and 1860. Redfield's first paper on the theory of storms was published in 1831, and was due to the fact of his having previously noticed, during a journey after a storm, that the trees were lying in opposite directions to those near his home. Espy supposed that the wind always blows inwards from the edge of the storm to a central point or line. He was a persistent opponent of Redfield. Dove's work on the theory of storms was essentially the same as Redfield's, but he also deals with the subject of winds in general. In a second article Mr. Rotch gives the description and history of the Sonnblick Mountain Observatory in Austria, and some of the preliminary results obtained. Mr. W. Upton contributes, on the part of the New England Meteorological Society, a very able paper on the remarkable storm which visited the eastern portion of the United States from the 11th to 14th of March last, and which is known as the New York "blizzard." Its peculiar characteristics were (1) the rapidity with which its energy was developed; (2) the excessive precipitation which accompanied it, principally as snow. West of the 72nd meridian it was almost wholly snow, piled up in immense drifts, making it absolutely impossible to measure it. East of this meridian it was snow and rain mixed. In a table giving the ratio of unmelted and melted snow it is shown that the density varied greatly, and furnishes proof that the method of assuming that 1·0 inch of snow equals 0·1 inch of rain is exceedingly erroneous. (3) The relatively small area of its maximum intensity. This storm was one of the most notable in this century over the Atlantic, and its behaviour over the ocean will be the subject of a special investigation by the United States Hydrographic Office.

THE Pilot Chart of the North Atlantic Ocean for the month of June shows that seven pronounced cyclonic storms passed over portions of the North Atlantic during May, but none appear to have traversed the entire ocean. Ice has been reported in increased quantity west of the 46th meridian, and, although confined for the most part to the coast of Newfoundland, it has been met with as far south as latitude 41°, in longitude 46° W. There has been a marked increase of fog over the Grand Banks and off the American coast north of Hatteras, while the amount encountered east of the 40th meridian has been unusually large. It is attributed almost entirely to the prevalence of southerly winds in that part of the ocean. During the past six months 51 vessels are known to have met with disaster in the North Atlantic ocean; the general drift of the logs of the great raft has been about east by south, and most of them are now about west-south-west from the Azores. Very few, if any, have drifted north of the 40th parallel. On April 10, latitude 41° 59'

N., longitude 47° 30′ W., Capt. McKay, of the s.s. *Pavonia*, saw a large waterspout travelling north-east at about 30 miles an hour. The great column of water reached up to a dense black, low-lying cloud, and was in shape like a huge hour-glass. It was accompanied by a terrific roaring. The spout broke, with a thunder and hail storm. Many pieces of ice, 4 to 6 inches in diameter, fell on board the ship. On the next day three distinct spouts were seen by another ship, about 250 miles north-east of the above position. These spouts gradually merged into one, and travelled out of sight.

FISHERMEN report that early on the morning of June 13 a waterspout was seen in the Grosses Haff, off Stettin. About 11.45 another one appeared near Dammausch. A steamer was, at the time, only 100 yards distant, and had to reverse her engines in order to escape it. Each lasted about a quarter of an hour.

SIR TERENCE O'BRIEN, Governor of Heligoland, in his report on the condition of that colony during the past year, states that at his instigation the Council of the Meteorological Department agreed to start a station there, and the Secretary, Mr. Scott, having gone over to superintend the putting up of the instruments, the observatory was established in August last, and will, he hopes, not only be of benefit to this branch of science, but will enable more accurate data than were formerly obtainable from the old and imperfect instruments at their disposal to be forthcoming in future Blue-book statistics.

IN a recording rain-gauge, recently devised by M. Brassard, the water passes from the bottom of the receiver into a centrally-pivoted trough, having each arm slightly depressed in the middle. It fills the two divisions alternately: the filled arm goes down, and empties itself into a lower trough, and the rocking thus caused is registered by an ordinary counter. Each rocking of the trough indicates one-tenth of a millimetre of water having fallen into the receiver. The instrument is designed to eliminate the error usually arising from evaporation.

ADVICES from the fishing village of Kerschkaranza, in the Kola Peninsula, on the White Sea, state that on January 5 a curious and destructive phenomenon occurred there. At 4 a.m. the inhabitants were awakened by a peculiar, dull, heavy detonation like that of distant artillery. Piled up to a height of several hundred feet, the ice—in consequence, no doubt, of the enormous pressure of the ocean ice without—was seen to begin moving from the north-west towards the shore. The gigantic ice wall moved irresistibly forward, and soon reached the shore and the village, which it completely buried, the ice extending a mile inland. The forward movement of the ice lasted four hours. No lives were lost.

ON April 29, when off the Westman Islands, Iceland, the captain of the Danish mail-steamer *Laura* threw overboard a letter written in Danish. On May 6 the letter was found in the stomach of a cod caught by a French fisherman off Reykjanæs, about 120 miles distant. The man showed it to the French Consul at Reykjavik, who submitted it to the captain of the *Laura*. It was much decomposed, but still readable.

A LANCE, an axe, a sword—all of bronze—an urn, a couple of whetstones, and some human remains have been found in a mound at Ogue, on the south-west coast of Norway.

AT the last meeting of the Asiatic Society of Japan, Dr. Knott read a biographical note on Ino Chukei, the great Japanese surveyor and cartographer. The following summary is taken from the report of the *Japan Weekly Mail*:—Ino was born in 1744, but did not begin his scientific career till he was fifty years of age. Up to that time he was a successful brewer. Towards the close of the century he went to Yedo, and there studied astronomy under the elder and younger Takahashi. The latter is the man who was put on his trial in 1830 for having exchanged maps of Yesso and Japan with Von Siebold for some books; the case, however, was never concluded, for he died in the meantime. In the year 1800, Ino began his work of surveying the coasts and islands of Japan, and for eighteen years he continued to labour at it, making in that time innumerable measurements of distance, and between 1100 and and 1200 direct measurements of latitude. The wonder is that he did so much with such rude instruments as he had, which resembled those in use in the West in the sixteenth and seventeenth centuries. The records of his survey were compiled in 1821, and were published, under the authority of the Tokio University, in book form in 1870. In fact, the charts he constructed have been the basis of all maps that have since been made. About six or seven years ago, Ino was raised by Imperial decree to the rank of "Posthumous," or Senior Fourth Class, an honour seldom held in his time by any but nobles, and, moreover, posthumous honours are very rarely given. Ino might be named the Japanese Picard, the French astronomer who made the first good calculation of the size of the earth. The instruments—an azimuth circle and a quadrant—used by Ino in his survey were destroyed by fire, but exact copies of them, constructed in 1828, were exhibited at the meeting.

ACCORDING to the report of the Inspector of Schools in Hong Kong for the past year, the total number of schools subject to Government supervision was 94, as against 45 in 1877 and 13 in 1867; the numbers of scholars for the corresponding years being respectively 5974, 3144, and 700. Of the 5974 pupils who attended schools under Government supervision in 1887, 4160 attended missionary schools, and 1814 the Government undenominational establishments. In the colony there are five classes of schools: (1) Chinese, where a purely Chinese education is given; (2) Romanized Chinese, in which a European education is given in the Chinese language; (3) Portuguese, where a European education is given in the Portuguese language only; (4) Anglo-Chinese schools, numbering eight, with 1160 scholars; (5) English schools, numbering six, with 688 scholars, in which the children are taught in the English language only. The Government Central School presented 384 boys for the annual examination, and of these 375 passed—that is, the very high percentage of 97·65. At this latter school the subjects taught are: reading, dictation, arithmetic, Chinese into English, English into Chinese, grammar, geography, map-drawing, composition, Euclid, algebra, mensuration, history, and Latin.

MESSRS. EYRE AND SPOTTISWOODE, as the Government publishers, have issued two new volumes of the "Report on the Scientific Results of the Voyage of the *Challenger*": vol. xxiv. Zoology (2 parts, text and plates), Report on the Crustacea Macrura; vol. xxv. Zoology, Report on the Tetractinellida.

A PAPER on "Wasted Sunbeams," by Dr. G. M. Smith, of New York, has just been reprinted from the *Medical Record*. The author's aim is to show that great advantages to health might be secured by a rearrangement of the upper stories of private dwellings. "Cannot architectural ingenuity," he asks, "coached by sanitary science, contrive some method of using the thousands of acres of housetops, so that roofs, now so useful in affording indoor protection from cold, sleet, and rain, can be made additionally useful, at certain seasons, by affording outdoor recreation and protection from invalidism? Cannot the same skill contrive new designs for the upper and most salutary stories of our dwellings; playing-rooms and sunning-rooms, especially adapted for the winter season, but so cleverly fashioned that too intense torrid beams can be excluded in summer?"

MR. J. ELLARD GORE has in the press a volume entitled "Planetary and Stellar Studies: papers on the Planets, Stars, and Nebulæ." It will be published shortly by Messrs. Roper and Drowley.

THE Fifteenth Annual Report of the progress of the Geological and Natural History Survey of Minnesota, by Mr. N. H. Winchell, State Geologist, has been issued. This Report relates chiefly to the geology of the iron-bearing rocks. It seems that during the last two years great interest has been manifested with regard to the iron industry in Northern Minnesota.

WE have received Part 3 of the twenty-first volume of the Journal and Proceedings of the Royal Society of New South Wales. Among the contents are papers on Port Jackson silt beds, by F. B. Gipps; some New South Wales tan-substances, parts 3 and 4, by J. H. Maiden, Curator of the Technological Museum, Sydney; soils and subsoils of Sydney and suburbs, by J. B. Henson; quarantine and small-pox, by J. Ashburton Thompson; on the presence of fusel-oil in beer, by W. M. Hamlet; autographic instruments used in the development of flying-machines, by Lawrence Hargrave.

PART I of the seventh volume of the "Encyclopædic Dictionary" (Cassell and Co.) has just been issued. This carefully-compiled work, as we have repeatedly had occasion to note, contains all the words in the English language, with a full account of their origin, meaning, pronunciation, and use. Great pains are taken to secure that scientific terms shall be properly explained.

MESSRS. OLIVER AND BOYD are about to publish "India in 1887, as seen by Robert Wallace, Professor of Agriculture and Rural Economy in the University of Edinburgh." The author was four months in India and Ceylon, and made inquiry as to the breeds of cattle and horses, and as to the condition of native agriculture, soils, irrigation, &c. The work contains 290 illustrations. Prof. Wallace especially wished to "learn in an unmistakable manner what fruits the Cirencester College training had borne."

WE have received Parts I and 2 of "The Speaking Parrots," by Dr. Karl Russ (Upcott Gill). Much useful information is given as to the purchase and reception of parrots, the cages in which they ought to be kept, their food, the best way of taming and training them, the preservation of their health, and as to their diseases.

AN Australian edition of Longmans' "School Geography," by Mr. George G. Chisholm, has just been issued. For this edition the sections on Australasia and the British Isles have been entirely re-written, and modifications have been made in other parts of the text with the view of calling attention to matters of special interest in Australia and New Zealand.

A NEW catalogue of mathematical works has been issued by Messrs. Dulau and Co.

THE current number of the *Technology Quarterly* opens with an interesting paper, by Mr. James P. Munroe, on the beginning of the Massachusetts Institute of Technology. The Institute was legally established on April 10, 1861, after more than two years of almost constant effort in the face of opposition and discouragement.

IT has been decided that the Miss Williams Scholarship for Women, of the annual value of £20, tenable for three years, shall be offered at the entrance scholarship examination at University College, Cardiff, on September 18, and that it may be held with a College exhibition. As it is specially intended to encourage the higher education of women in Wales, preference will be given to the children of Welsh parents.

A COLLECTION of American pottery for the American National Museum is about to be made by Dr. David T. Day of the United States Geological Survey. *Science* says that the collection of Sèvres pottery presented by the French Government is an exceedingly fine one, as is also that of Japanese ceramics; and the department of Indian pottery is not approached elsewhere in the world. But the Museum possesses very little modern American pottery.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. A. B. Parker; a Larger Hill-Mynah (*Gracula intermedia*) from North India, presented by Mrs. M. von Kornatzki; two Naked-footed Owlets (*Athene noctua*) from France, presented by Miss Pierce; a Swainson's Lorikeet (*Trichoglossus novæ-hollandiæ*) from Australia, presented by Mr. H. A. Hankey; two Loggerhead Ducks (*Tachyeres cinereus*) from the Falkland Islands, presented by Mr. Archibald McCall; a Duyker-bok (*Cephalophus mergens* ♀) from South Africa, a Red-legged Partridge (*Caccabis rufa*), a Barbary Partridge (*Caccabis petrosa*), five —— Pigeons (*Columba ballii*) from Teneriffe, deposited; a Bennett's Wallaby (*Halmaturus bennetti* ♀), two Long-fronted Gerbilles (*Gerbillus longifrons*) born in the Gardens; a Yellow-legged Herring Gull (*Larus cachinnans*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

ROTATION PERIOD OF THE SUN FROM FACULÆ.—The fifth part of vol. iv. of the Publications of the Astrophysical Observatory at Potsdam has recently appeared, and contains a determination by Dr. J. Wilsing of the rotation period of the sun from observations of faculæ. The previous determinations of the solar rotation have been based upon observations of the spots, or upon the relative displacement of lines in the spectra of the east and west limbs, for, as faculæ can usually only be seen well when near the limb, and therefore can seldom be watched for more than three consecutive days, and as they often undergo rapid changes, they did not seem well suited for such a discussion. Their irregular and often straggling shapes, too, render measures of their positions much less precise than those of spots. Notwithstanding these difficulties Dr. Wilsing's inquiry seems to have met with a measure of success. Of the faculæ shown on the solar photographs taken at Potsdam from 1884 March 14 to August 31, 144 groups were seen at three or more different epochs, at intervals of one or more semi-rotations. Arranging these according to their distribution in solar latitude, in zones of 3° wide, Dr. Wilsing finds practically the same rotation period for each zone from + 24° to − 33°, the difference from the mean of the daily angular motion only exceeding 2′ in a single instance, and in many cases amounting only to 20″ or 30″. As these differences are so small and follow no law, it would appear that, whilst, as Carrington and Spoerer have shown, the different spot zones have different rates of rotation, the layer of the faculæ rotates as a whole. Since the faculæ are certainly at a higher level than the spots, this conclusion is one which will fail to be accepted until we have much further and more convincing evidence than we have at present. In the present discussion it sometimes happens that a group of faculæ is considered as identical with an earlier group seen two or three semi-rotations earlier, when the same part of the sun has been seen in the interval, but without showing the group, although the district has been favourably presented for displaying faculæ. In such a case, and particularly if several semi-rotations have elapsed, the two groups will be identified or not according to the rotation period assumed; so that if a single rotation period for the whole sun be assumed in the preliminary reductions of position for the sake of identification of the groups, there will be an inevitable tendency towards a single rotation period in the final result.

The mean daily angular velocity given by the faculæ is 14° 16′ 11″·3, corresponding to a sidereal period of 25d. 5h. 28m. 12s., the values for the northern and southern hemisphere, taken separately, differing only by 11″·5. It is worthy of note that this corresponds to the rotation period of spots about latitude 10°, as given alike by Carrington and Spoerer's formulæ, and that the two zones 5° to 15° yield the greater number both of spots and faculæ which are available for these investigations. The present discussion, with whatever reserve its conclusions are to be accepted, is, however, both interesting and important and should lead to further inquiries in the same direction, when a more extended series of observations should be laid under contribution.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *JULY* 1-7.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 1

Sun rises, 3h. 50m.; souths, 12h. 3m. 38·5s.; sets, 20h. 17m.: right asc. on meridian, 6h. 43·5m.; decl. 23° 4′ N. Sidereal Time at Sunset, 14h. 58m.

Moon (at Last Quarter July 1, 4h.) rises, 0h. 8m.; souths, 6h. 9m.; sets, 12h. 22m.: right asc. on meridian, 0h. 47·5m.; decl. 0° 16′ S.

GEOGRAPHICAL NOTES.

AT Monday's meeting of the Royal Geographical Society, Lieutenant Wissmann was present, and was formally presented by the President with the gold medal which has been awarded to him by the Society for his exploring work in Africa. Lieutenant Wissmann afterwards gave some account of his explorations in the region to the south of the great Congo bend. He began his African work eight years ago in company with the late Dr. Pogge, with whom he traversed the region lying between Loanda and Nyangwe on the Upper Congo. The Kassai and several others of the great rivers that flow north to the Congo were crossed, and a large area of new country, thickly covered with an interesting population, opened up. Dr. Pogge returned to the west coast, whilst Lieutenant Wissmann proceeded from Nyangwe to Zanzibar. He returned to Africa a second time in the service of the King of the Belgians, and in company with Dr. Wolf, Lieutenant von François, and others, made his way again from Loanda into the interior. During the period between 1884 and 1887, Lieutenant Wissmann explored the Great Kassai, and did much to unravel the complicated system of rivers, of which it is the centre. Moreover, his observations on the people, as well as the fauna and flora, render his work of great scientific value. He again crossed to Nyangwe, and, by Lakes Tanganyika and Nyassa, reached the east coast at the mouth of the Zambesi. He returned to Europe in the autumn of last year, with his health shattered, and was compelled to go to Madeira to recruit. Now Lieutenant Wissmann returns to Germany, and will no doubt there work out the results of his eight years' work in Africa. Already one volume has been published, dealing with the exploration of the Kassai-Sankuni.

CAPTAIN W. J. L. WHARTON, the Hydrographer, also read a paper at Monday's meeting of the Royal Geographical Society. He described the results of a very complete examination which has recently been made of Christmas Island, in the Indian Ocean, some 200 miles south of the western end of Java. The island is a peculiar one, and extremely difficult to explore. It consists apparently of high cliffs of coral, covered with the densest vegetation. After describing the results of examination by Captain Aldrich and others, Captain Wharton concluded by giving a summary of the conclusions to be drawn. We have, he said, a high island, on the surface of which, wherever examined, we find limestone, bearing in most places the appearance of coral origin, though in some specimens the shells of the Foraminifera abound, and in none of them have direct evidences of coral structure been detected. It must be remembered, however, that coral limestone becomes so altered by the deposition of lime by infiltration, that a large surface of it may be searched before a piece retaining its coralline structure is found, and that the specimens sent home are very small. From the description of Captain Aldrich, who is well acquainted with coral formations, it may be taken for granted that the majority of this rock is of coral origin. The rock forming the summit is of this structureless character. In two spots, and at the bottom of a hole in the summit of the ridge, we have volcanic rock. The island is very steep on all sides, great depths being found close to the cliffs, while on all sides, at a short distance, soundings over three miles in depth were obtained. It appears, then, most probable that Christmas Island is founded on a volcanic mound which rose from the bottom to a certain distance from the surface of the sea; that Foraminifera shells dying on the surface were rained upon it in sufficient number to form a stratum, since solidified into limestone rock; that as the mound neared the surface, corals built upon it, and it is possible from the sketch of the island, and from Captain Aldrich's description of the slope of the ridge inwards, that it first assumed an atoll form. This, however, is a mere inference from probabilities. The island was next gradually upheaved, the coral growing outwards on the gentle slope until a period of immobility ensued long enough to permit the waves to erode the upper cliff. Another short period of upheaval, and one of stationary character ensued, when the second cliff was worn away. A third interval of upheaval, probably longer than the others, and then a second stand, when the lowest and highest inland cliff was formed. Finally, another lift was given, and the stationary period now in existence completed the process. The volcanic stones found in various places on the higher parts of the island point to a thinning of the limestone covering in those places. Denudation has worn away the limestone, and the volcanic core is consequently exposed. Man has never lived on Christmas Island, nor would it be a pleasant residence, as, apart from the fact that there is no water—the rain sinking into the limestone rock—the extreme discomfort of locomotion, and the absence of any harbour whence the produce that might possibly be raised could be conveniently shipped, will deter any settlers from seeking a home there until other more favourable spots are occupied. There is no other instance with which Captain Wharton is acquainted of an island of this height retaining its coral covering so intact. Coral reefs have been found at heights of 1000 feet in Cuba, in the Fiji Islands, and other places; but in all cases they are mere fragments, and the intervening spaces show no signs of coral. Further and closer investigation may record more direct evidence of its structure, and of the successive steps which have resulted in its present condition; but the Hydrographer thought our present knowledge of Christmas Island was sufficient to make this short notice interesting to the Society.

DIFFRACTION OF SOUND.[1]

THE interest of the subject which I propose to bring before you this evening turns principally upon the connection or analogy between light and sound. It has been known for a very long time that sound is a vibration; and everyone here knows that light is a vibration also. The last piece of knowledge, however, was not arrived at so easily as the first; and one of the difficulties which retarded the acceptance of the view that light is a vibration was that in some respects the analogy between light and sound seemed to be less perfect than it should be. At the present time many of the students at our schools and universities can tell glibly all about it; yet this difficulty is one not to be despised, for it exercised a determining influence over the great mind of Newton. Newton, it would seem, definitely rejected the wave-theory of light on the ground that according to such a theory light would turn round the corners of obstacles, and so abolish shadows, in the way that sound is generally supposed to do. The fact that this difficulty seemed to Newton to be insuperable is, from the point of view of the advancement of science, very encouraging. The difficulty which stopped Newton two centuries ago is no difficulty now. It is well known that the question depends upon the relative wave-lengths in the two cases. Light-shadows are sharp under ordinary circumstances, because the wave-length of light is so small; sound-shadows are usually of a diffused character, because the wave-length of sound is so great. The gap between the two is enormous. I need hardly remind you that the wave-length of C in the middle of the musical scale is about 4 feet. The wave-length of the light with which we are usually concerned, the light towards the middle of the spectrum, is about the forty-thousandth of an inch. The result is that an obstacle which is immensely large for light may be very small for sound, and will therefore behave in a different manner.

That light-shadows are sharp is a familiar fact, but as I can prove it in a moment I will do so. We have here light from the electric arc thrown on the screen; and if I hold up my hand thus we have a sharp shadow at any moderate distance, which shadow can be made sharper still by diminishing the source of light. Sound-shadows, as I have said, are not often sharp; but I believe that they are sharper than is usually supposed, the reason being that when we pass into a sound-shadow—when, for example, we pass into the shade of a large obstacle, such as a building—it requires some little time to effect the transition, and the consequence is that we cannot make a very ready comparison between the intensity of the sound before we enter and its diminution afterwards. When the comparison is made under more favourable conditions, the result is often better than would have been expected. It is, of course, impossible to perform experiments with such obstacles before an audience, and the shadows which I propose to show you to-night are on a much smaller scale. I shall take advantage of the sensitiveness of a flame such as Professor Tyndall has often used here—a flame sensitive to the waves produced by notes so exceedingly high as to be inaudible to the human ear. In fact, all the sounds with which I shall deal to-night will be inaudible to the audience. I hope that no quibbler will object that they are therefore not sounds: they are in every respect analogous to the vibrations which produce the ordinary sensations of hearing.

I will now start the sensitive flame. We must adjust it to a reasonable degree of sensitiveness. I need scarcely explain the mechanism of these flames, which you know are fed from a special gas-holder supplying gas at a high pressure. When the pressure is too high, the flame flares on its own account (as this one is doing now), independently of external sound. When the pressure is somewhat diminished, but not too much so—when the flame "stands on the brink of the precipice" were, I think, Tyndall's words—the sound pushes it over, and causes it to flare; whereas, in the absence of such sound, it would remain erect and unaffected. Now, I believe, the flame is flaring under the action of a very high note that I am producing here. That can be tested in a moment by stopping the sound, and seeing whether the flame recovers or not. It recovers now. What I want to show you, however, is that the sound-shadows may be very sharp. I will put my hand between the flame and the source of sound, and you will see the difference. The flame is at present flaring; if I put my hand here, the flame recovers. When the adjustment is correct, my hand is a sufficient obstacle to throw a most conspicuous shadow. The flame is now in the shadow of my hand, and it recovers its steadiness: I move my hand up, the sound comes to the flame again, and it flares. When the conditions are at their best, a very small obstacle is sufficient to make the entire difference, and a sound-shadow may be thrown across several feet from an obstacle as small as the hand. The reason of the divergence from ordinary experience here met with is, that while the hand is a fairly large obstacle in comparison with the wave-length of the sound I am here using, it would not be a sufficiently large obstacle in comparison with the wave-lengths with which we have to do in ordinary life and in music.

Everything then turns upon the question of the wave-length. The wave-length of the sound that I am using now is about half an inch. That is its complete length, and it corresponds to a note that would be very high indeed on the musical scale. The wave-length of middle C being four feet, the C one octave above that is two feet; two octaves above, one foot; three octaves above, six inches; four octaves, three inches; five octaves, one and a half inch; six octaves, three-quarters of an inch; between that and the next octave, that is to say, between six and seven octaves above middle C, is the pitch of the note that I was just now using. There is no difficulty in determining what the wave-length is. The method depends upon the properties of what are known as stationary sonorous waves as opposed to progressive waves. If a train of progressive waves are caused to impinge upon a reflecting wall, there will be sent back or reflected in the reverse direction a second set of waves, and the co-operation of these two sets of waves produces one set or system of stationary waves; the distinction being that, whereas in the one set the places of greatest condensation are continually changing and passing through every point, in the stationary waves there are definite points for the places of greatest condensation (nodes), and others distinct and definite (loops) for the places of greatest motion. The places of greatest variation of density are the places of no motion: the places of greatest motion are places of no variation of density. By the operation of a reflector, such as this board, we obtain a system of stationary waves, in which the nodes and loops occupy given positions relatively to the board.

You will observe that as I hold the board at different distances behind, the flame rises and falls—I can hardly hold it still enough. In one position the flame rises, further off it falls again; and as I move the board back the flame passes continually from the position of the node—the place of no motion—to the loop or place of greatest motion and no variation of pressure. As I move back, the aspect of the flame changes; and all these changes are due to the reflection of the sound-waves by the reflector which I am holding. The flame alternately ducks and rises, its behaviour depending npon the different action of the nodes and loops. The nodes occur at distances from the reflecting wall, which are even multiples of the quarter of a wave-length; the loops are, on the other hand, at distances from the reflector which are odd multiples, bisecting therefore the positions between the loops. I will now show you that a very slight body is capable of acting as a reflector. This is a screen of tissue-paper, and the effect will be apparent when it is held behind the flame and the distances are caused to vary. The flame goes up and down, showing that a considerable proportion of the sonorous intensity incident upon the paper screen is reflected back upon the flame; otherwise the exact position of the reflector would be of no moment. I have here, however, a different sort of reflector. This is a glass plate —I use glass so that those behind may see through it—and it will slide upon a stand here arranged for it. When put in this position the flame is very little affected: the place is what I call a node—a place where there is great pressure variation, but no vibratory velocity. If I move the glass back, the flame becomes vigorously excited: that position is a loop. Move it back still more, and the flame becomes fairly quiet; but you see that as the plate travels gradually along, the flame goes through these evolutions as it occupies in succession the position of a node or the position of a loop. The interest of this experiment for our present purpose depends upon this—that the distances through which the glass plate, acting as a reflector, must be successively moved in order to pass the flame from a loop to the next loop, or from a node to the consecutive node, is in each case half the wave-length; so that by measuring the space through which the plate is thus withdrawn one has at once a measurement of the wave-length, and consequently of the pitch of the sound, though one cannot hear it.

[1] Lecture delivered by Lord Rayleigh, F.R.S., at the Royal Institution, on January 20, 1888.

The question of whether the flame is excited at the nodes or at the loops—whether at the places where the pressure varies most, or at those where there is no variation of pressure, but considerable motion of air—is one of considerable interest from the point of view of the theory of these flames. The experiment could be made well enough with such a source of sound as I am now using; but it is made rather better by using sounds of a lower pitch, and therefore of greater wave-length, the discrimination being then more easy. Here is a table of the distances which the screen must be from the flame in order to give the maximum and the minimum effect, the minimum being practically nothing at all.

Table of Maxima and Minima.

Max.	Min.
1·1	
	3·0
4·5	
	5·9
7·5	
	8·9
10·3	
	11·7
13·0	
	14·7
15·9	

The distance between successive maxima or successive minima is very nearly 3 cm., and this is accordingly half the length of the wave.

But there is a further question behind. Is it at the loops or is it at the nodes that the flame is most excited? The table shows what the answer must be, because the nodes occur at distances from the screen which are even multiples, and the loops at distances which are odd multiples; and the numbers in the table can be explained in only one way—that the flame is excited at the loops corresponding to the odd multiples, and remains quiescent at the nodes corresponding to the even multiples. This result is especially remarkable, because the ear, when substituted for the flame, behaves in the exactly opposite manner, being excited at the nodes and not at the loops. The experiment may be tried with the aid of a tube, one end of which is placed in the ear, while the other is held close to the burner. It is then found that the ear is excited the most when the flame is excited least, and *vice versâ*. The result of the experiment shows, moreover, that the manner in which the flame is disintegrated under the action of sound is not, as might be expected, symmetrical in regard to the axis of the flame. If it were symmetrical, it would be most affected by the symmetrical cause—namely, the variation of pressure. The fact being that it is most excited at the loop, where there is the greatest vibratory velocity, shows that the method of disintegration is unsymmetrical, the velocity being a directed quantity. In that respect the theory of these flames is different from the theory of the water-jets investigated by Savart, which resolve themselves into detached drops under the influence of sonorous vibration. The analogy fails at this point, and it has been pressed too far by some experimenters on the subject. Another simple proof of the correctness of the result of our experiment is that it makes all the difference which way the burner is turned in respect of the direction in which the sound-waves are impinging upon it. If the phenomenon were symmetrical, it would make no difference if the flame were turned round upon its vertical axis. But we find that it does make a difference. This is the way in which I was using the flame, and you see that it is flaring strongly. If I now turn the burner round through a right angle, the flame stops flaring. I have done nothing more than turn the burner round and the flame with it, showing that the sound-waves may impinge in one direction with great effect, and in another direction with no effect. The sensitiveness occurs again when the burner is turned through another right angle; after three right angles there is another place of no effect; and after a complete revolution of the flame the original sensitiveness recurs. So that if the flame were stationary, and the sound-waves, came, say, from the north or south, the phenomena would be exhibited; but if they came from the east or west, the flame would make no response.

This is of convenience in experimenting, because, by turning the burner round, I make the flame almost insensitive to a sound, and I am now free to show the effect of any sound that may be brought to it in the perpendicular direction. I am going to use a very small reflector—a small piece of looking-glass. Wood would do as well; but looking-glass facilitates the adjustment, because my assistant, by seeing the reflection, will be able to tell me when I am holding it in the best position. Now, the sound is being reflected from the bit of glass, and is causing the flame to flare, though the same sound, travelling a shorter distance and impinging in another direction, is incompetent to produce the result (Fig. 1).

I am now going to move the reflector to and fro along the line perpendicular to that joining the source and the burner, all the while maintaining the adjustment, so that from the position of the source of sound the image of the flame is seen in the centre of the mirror. Seen from the source, it is still as central as before, but it has lost its effect, and as I move it to and fro I produce cycles of effect and no effect. What is the cause of this? The question depends upon something different from what I have been speaking of hitherto; and the explanation is, that we are here dealing with a diffraction phenomenon. The mirror is a small one, and the sound-waves which it reflects are not big enough to act in the normal manner. We are really dealing with the same sort of phenomena as arise in optics when we use small pin-holes for the entrance of our light. It is not very easy to make the experiment in the present form quite simple, because the mirror would have to be withdrawn, all the while maintaining a somewhat complicated adjustment. In order to raise the question of diffraction in its simplest shape, we must have a direct course for the sound between its origin and the place of observation, and interpose in the path a screen perforated with such holes as we desire to try.

The screen I propose to use is of glass. It is a practically perfect obstacle for such sounds as we are dealing with; but it is perforated here with a hole (20 cm. diameter), rendered more evident to those at a distance by means of a circle of paper pasted round it. The edge of the hole corresponds to the inner circumference of the paper. We shall thus be able to try the effect of different-sized apertures, all the other circumstances remaining unchanged. The experiment is rather a difficult one before an audience, because everything turns on getting the exact adjustment of distances relatively to the wave-length. At present the sound is passing through this comparatively large hole in the glass screen, and is producing, as you see, scarcely any effect upon the flame situated opposite to its centre. But if (Fig. 2) I diminish the size of the hole by holding this circle of zinc (perforated with a hole 14 cm. in diameter) in front of it, it is seen that, although the hole is smaller, we get a far greater effect. That is a fundamental phenomenon in diffraction. Now I reopen the larger hole, and the flame becomes quiet. So that it is evident that in this case the sound produces a greater effect in passing through a small hole than in passing through a larger one. The experiment may be made in another way, by obstructing the central in place of the marginal part of the aperture in the glass. When I hold this unperforated disk of zinc (14 cm. in diameter) centrically in front, we get a greater effect than when the sound is allowed to pass through both parts of the aperture. The flame is now flaring vigorously under the action of the sonorous waves passing the marginal part of the aperture, whereas it will scarcely flare at all under the action of waves passing through both the marginal and the central hole.

This is a point which I should like to dwell upon a little, for it lies at the root of the whole matter. The principle upon which it depends is one that was first formulated by Huygens, one of the leading names in the development of the undulatory theory of light. In this diagram (Fig. 3) is represented in section the different parts of the obstacle. C represents the source of sound, B represents the flame, and A P Q is the screen. If we choose a point, P, on this screen, so that the whole distance from B to C, reckoned through P, viz. B P C, exceeds the shortest distance B A C by exactly half the wave-length of the sound, then the circular area, whose radius is A P, is the first zone. We take next another point, Q, so that the whole distance B Q C exceeds the previous one by half a wave-length. Thus we get the second zone represented by P Q. In like manner, by taking different points in succession such that the last distance taken exceeds the previous one every time by half a wave-length, we may map out the whole of the obstructing screen into a series of zones called Huygens' zones. I have here a material embodiment of that notion, in which the zones are actually cut out of a piece of zinc. It is easy to prove that the effects of the parts of the wave traversing the alternate zones are opposed; that whatever may be the effect of the first zone, A P, the exact opposite will be the effect of P Q, and so on. Thus, if A P and P Q are both allowed to operate, while all beyond Q is cut off, the waves will neutralize one another, and the effect will be immensely less than if A P or P Q operated alone. And that is what we saw just now. When I used the inner aperture only, a comparatively loud sound acted upon the flame. When I added to that inner aperture the additional aperture P Q, the sound disappeared, showing that the effect of the latter was equal and opposite to that of A P, and that the two neutralized each other.

[If A C = a, A B = b, A R = x, wave-length = λ, the value of x for the external radius of the nth zone is

$$x^2 = n\lambda \frac{a + b}{ab};$$

or, if $a = b$,

$$x^2 = \tfrac{1}{2}n\lambda a.$$

With the apertures used above, $x^2 = 49$ for $n = 1$; $x^2 = 100$ for $n = 2$; so that

$$\lambda a = 100,$$

the measurements being in centimetres. This gives the suitable distances, when λ is known. In the present case $\lambda = 1·2$, $a = 83$.]

Closely connected with this there is another very interesting experiment, which can easily be tried, and which has also an important optical analogy. I mean the experiment of the shadow thrown by a circular disk. If a very small source of light be taken—such a source as would be produced by perforating a thin plate in the shutter of the window of a dark room with a pin, and causing the rays of the sun to enter horizontally—and if we interpose in the path of the light a small circular obstacle, and then observe the shadow thrown in the rear of that obstacle, a very remarkable peculiarity manifests itself. It is found that in the centre of the shadow of the obstacle, where the darkness might

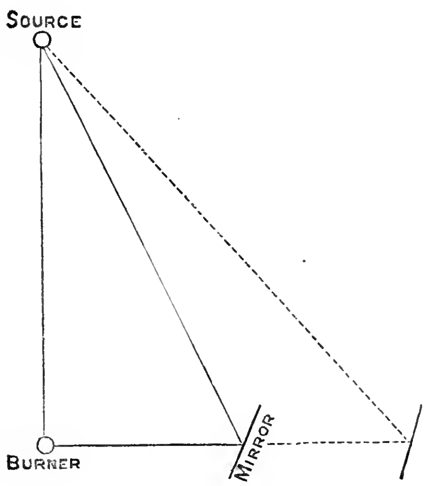

FIG. 1.

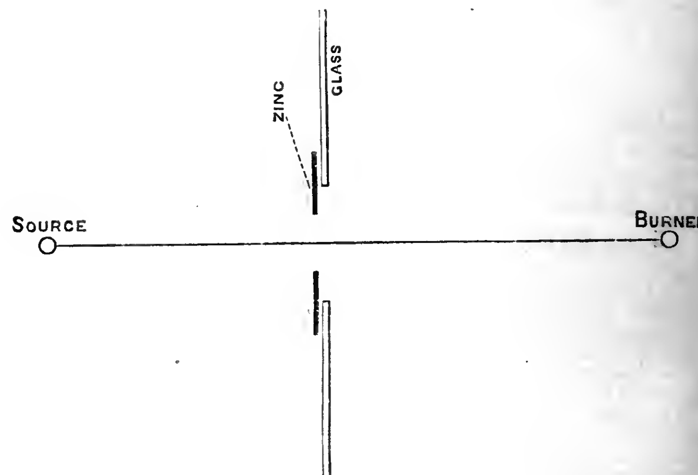

FIG. 2.

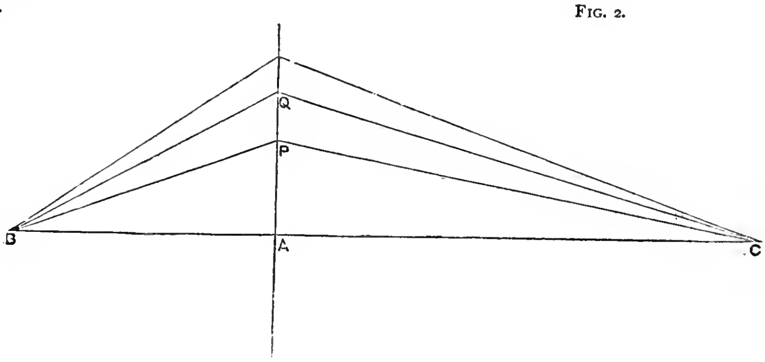

FIG. 3.

be expected to be greatest, there is, on the contrary, no darkness at all, but a bright spot, a spot as bright as if no obstacle intervened in the course of the light. The history of this subject is curious. The fact was first observed by Delisle in the early part of the eighteenth century, but the observation fell into oblivion. When Fresnel began his important investigations, his memoir on diffraction was communicated to the French Academy, and was reported on by the great mathematician Poisson. Poisson was not favourably impressed by Fresnel's theoretical views. Like most mathematicians of the day, he did not take kindly to the wave theory; and in his report on Fresnel's memoir, he made the objection that if the method were applied, as Fresnel had not then done, to investigate what should happen in the shadow of a circular obstacle, it brought out this paradoxical result, that in the centre there would be a bright point. This was regarded as a *reductio ad absurdum* of the theory. All the time, as I have mentioned, the record of Delisle's observations was in existence. The remarks of Poisson were brought to the notice of Fresnel, the experiment was tried, and the bright point was rediscovered, to the gratification of Fresnel and the confirmation of his theoretical views. I don't propose to attempt the optical experiment now, but it can easily be tried in one's own laboratory. A long room or passage must be darkened: a fourpenny bit may be used as the obstacle, strung up by three hairs attached by sealing-wax. When the shadow of the obstacle is received on a piece of ground glass, and examined from behind with a magnifying lens, the bright spot will be seen without much difficulty. But what I propose to show you is the corresponding phenomenon in the case of sound. Fresnel's reasoning is applicable, word for word, to the phenomena we are considering just as much as to that which he, or rather Poisson, had in view. The disk (Fig. 4), which I shall hang up now between the source of sound and the flame, is of glass. It is about 15 inches in diameter. I believe the flame is flaring now from being in the bright spot. If I make a small motion of the disk, I shall move the bright spot and the effect will disappear. I am pushing the disk away now, and the flaring has stopped. The flame is still in the shadow of the disk, but not at the centre. I bring the disk back again, and when the flame comes into the centre it flares again vigorously. That is the phenomenon which was discovered by Delisle and confirmed by Arago and Fresnel, but mathematically it was suggested by Poisson.

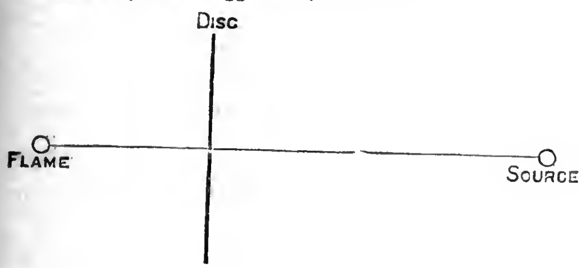

FIG. 4.

Poisson's calculation related only to the very central point in the axis of the disk. More recently the theory of this experiment has been very thoroughly examined by a German mathematician, Lommel; and I have exhibited here one of the curves given by him embodying the results of his calculations on the subject (Fig. 5).

The abscissæ, measured horizontally, represent distances drawn outwards from the centre of the shadow O; the ordinates measure the intensity of the light at the various points. The maximum intensity OA is at the centre. A little way outwards, at B, the intensity falls almost, but not quite, to zero. At C there is a revival of intensity, indicating a bright ring; and further out there is a succession of subordinate fluctuations. The curve on

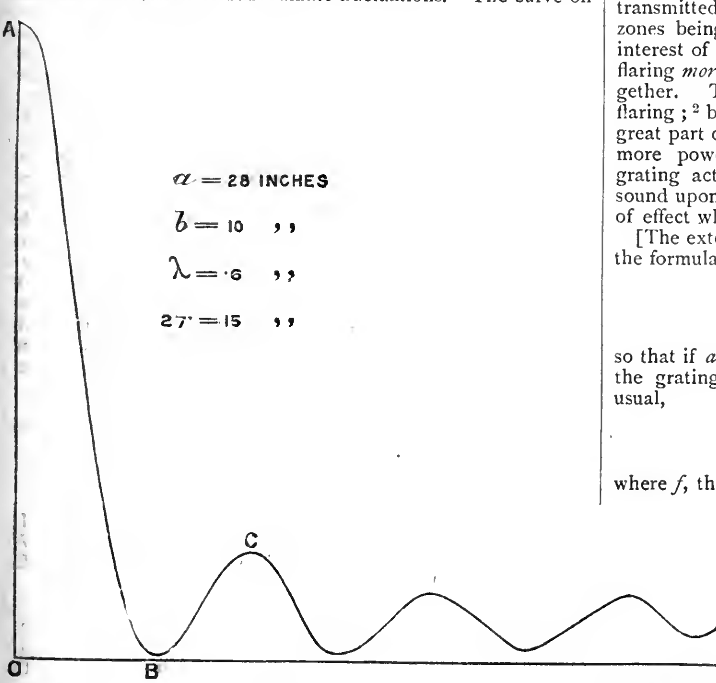

FIG. 5.

the other side of OA would of course be similar. This curve corresponds to the distances and proportions indicated. a is the distance between the source of sound and the disk; b is the distance between the disk and the flame, the place where the intensity is observed. The numbers given are taken from the notes of an experiment which went well. If we can get our flame to the right point of sensitiveness, we may succeed in bringing into view not only the central spot, but the revived sound which occurs after you have got away from the central point and have passed through the ring of silence. There is the loud central point. If I push the disk a little, we enter the ring of silence, B;[1] a little further, and the flame flares again, being now at C.

Although we have thus imitated the optical experiment, I must not leave you under the idea that we are working under the same conditions that prevail in optics. You see the diameter of my disk is 15 inches, and the length of my sound-wave is about half an inch. My disk is therefore about thirty wave-lengths in diameter, whereas the diameter of a disk representing thirty wave-lengths of light would be only about $\frac{1}{1000}$ inch. Still, the conditions are sufficiently alike to get corresponding effects, and to obtain this bright point in the centre of the shadow conspicuously developed.

I will now make an experiment illustrating still further the principle of Huygens' zones, which I have already roughly sketched. I indicated that the effect of contiguous zones was equal and opposite, so that the effect of each of the odd zones is one thing, and of the even zones the opposite thing. If we can succeed in so preparing a screen as to fit the system of zones, allowing the one set to pass, and at the same time intercepting the other set, then we shall get a great effect at the central point, because we shall have removed those parts which, if they remained, would have neutralized the remaining parts. Such a system has been cut out of zinc, and is now hanging before you. When the adjustments are correct, there will be produced, under the action of that circular grating, an effect much greater than would result if the sound-waves were allowed to pass on without any obstruction. The only point difficult of explanation is as to what happens when the system of zones is complete, and extends to infinity, viz. when there is no obstruction at all. In that case it may be proved that the aggregate effect of all the zones is, in ordinary cases, half the effect that would be produced by any one zone alone, whereas if we succeed in stopping out a number of the alternate zones, we may expect a large multiple of the effect of one zone. The grating is now in the right position, and you see the flame flaring strongly, under the action of the sound-waves transmitted through these alternate zones, the action of the other zones being stopped by the interposition of the zinc. But the interest of the experiment is principally in this, that the flame is flaring *more* than it would do if the grating were removed altogether. There is now, without the grating, a very trivial flaring;[2] but when the grating is in position again—though a great part of the sound is thereby stopped out—the effect is far more powerful than when no obstruction intervened. The grating acts, in fact, the part of a lens. It concentrates the sound upon the flame, and so produces the intense magnification of effect which we have seen.

[The exterior radius of the nth zone being x, we have, from the formula given above—

$$\frac{1}{a} + \frac{1}{b} = \frac{n\lambda}{x^2};$$

so that if a and b be the distances of the source and image from the grating, the relation required to maintain the focus is, as usual,

$$\frac{1}{a} + \frac{1}{b} = \frac{1}{f},$$

where f, the *focal length*, is given by—

$$f = \frac{x^2}{n\lambda}.$$

In the actual grating, eight zones (the first, third, fifth, &c.) are occupied by metal. The radius of the first zone, or central circle, is 3 inches, so that $x^2/n = 9$. The focal length is necessarily a function of λ. In the present case $\lambda = \frac{1}{2}$ inch nearly, and therefore $f = 18$ inches. If a and b are the same, each must be made equal to 36 inches.]

SCIENTIFIC SERIALS.

Revue d'Anthropologie, troisième série, tome iii., 1888 (Paris).—Stratigraphic palæontology in relation to man, by M. Marcellin Boule. Rejecting as unauthenticated all evidence of human existence in the Tertiary age, the author considers the

[1] With the data given above the diameter of the silent ring is two-thirds of an inch.

[2] Under the best conditions the flame is absolutely unaffected.

grounds on which we may assume that the so-called Saint Acheul flint instruments, found in alluvial beds of undoubted Quaternary origin, supply the most ancient testimony of man's presence on the surface of the earth. While attaching great importance to the careful elucidation of the chronological order in which the oldest traces of man appear relatively to the different series of the Quaternary formations, he points out the imminent risk of losing the few opportunities which still remain of studying this connection between the objects found and the nature and order of sequence of the beds in which they were deposited, owing to the most interesting finds having long been made to swell the collections of our Museums without reference to their value as exponents of the problems of our primitive history. M. Marcellin Boule considers that palæologists have erred in assuming that all beds containing the same fossil remains must necessarily belong to the same epoch, and that sufficient importance has not been attached to the fact that the same deposit often contains a mixture of animal forms belonging both to so-called northern and southern types. In explanation of these and many other anomalous phenomena, he thinks we may derive important help from a careful consideration of the intermittence and recurrence of glacial action. In regard to this point he recognizes the great value of the labours of British and American as well as Scandinavian and German geologists when compared with those of the majority of their French *confrères*; and, following the lead of our own palæontologists, he refuses to believe that any traces of human existence can be referred to pre-glacial ages, although some may perhaps be assigned to inter-glacial periods; while he considers that in certain northern lands, as Denmark and Southern Sweden, where there is a complete absence of Palæolithic objects, their non-appearance may be explained by the ice-covering not having been entirely removed in these regions till the dawn of the age of polished stone.—The tibia in the Neanderthal race, by Prof. Julien Fraipont. As a further exposition of the views which the author, in concert with M. Lohest, had expressed in regard to the effect on the maintenance of the vertical position of the obliquity and curvature of the femur in the "men of Spy," he now attempts to show, from the observations of others, and his own anatomical experiments, that in this inclination of the head of the femur we have a characteristic common to the anthropoids. An ingeniously devised series of determinations of the variations of the axis of the head of the tibia in recent man, the men of Spy, the gorilla, and other anthropoids, shows the gradual straightening of the axis as we ascend from the latter to existing man, in whom there is a well-marked tendency to the fusion of the axis of the head of the tibia with that of the body. From a careful comparison of the gradual anatomical changes presented in man since his earliest representative appeared in the Quaternary age, M. Fraipont believes we are justified in assuming that the human race has progressively acquired a more and more vertical posture.—On the population of the ancient Pagus-Çap-Sizun, "Cape du Raz," by MM. Le Carguet and P. Topinard. In considering the map of France from an ethnographic point of view, French anthropologists are generally agreed in regarding as specially Celtic the region which includes Brittany, Auvergne, and the entire mass of mountains extending through Central France and Savoy. The population of the eastern portion of this region is more brachycephalic than that of the western, which has been largely affected by admixture with the blonde, tall, dolichocephalic races whose presence is traceable everywhere in Europe, although more definitely the further north we go. This admixture of types is most strongly marked in Brittany, where French is the spoken tongue in Haute-Bretagne, and Breton (apparently a dialect derived from an ancient Kymric language) the predominant tongue in Basse-Bretagne. Among the many interesting localities of the latter region, special attention is due to Pointe du Raz, which, from the nature of its rocky boundaries on the land side, and its position further west than any other in France, has been virtually cut off from communication with the rest of the country, in consequence of which its population presents relatively fewer marks of mixed origin. M. Topinard supplies an interesting report on the geological, historical, and ethnological characteristics of the Cape du Raz district, and thus enhances the value of the series of observations regarding the population of this far west of France which have been supplied by M. Le Carguet, and may be generally summarized as leading to the inference that the "Capiste" race is essentially Breton in regard to the predominance of blue eyes with dark hair, and their generally low stature, these characteristics being associated with a disposition in which courage and energy are blended with strongly marked avarice and a love of greed; while in other respects they show evidence of a strongly-marked Celtic type.—Heredity in political economy, by M. de Lapouge. In this sequel to his former articles on "Inequality among Men," the author urges that it is the duty of the State to use all means at its disposal to eliminate the degenerate, and multiply the favoured elements of which the community is composed. As an ultra-pessimist in regard to the advance of inferior races through civilization, he points to the small effect which thousands of years have effected in the natives of the Black Continent. To him, equality and fraternity are mere delusive terms, based on an insufficient estimate of the force of the immutable laws of Nature, from amongst which we cannot exclude natural selection and survival of the fittest. As the avowed opponent of the doctrine of the amalgamation of types, and the production of permanent hybrids, he proclaims it as his opinion that, if the higher races are not to be exterminated by the lower, they must ally themselves solely with their own dolichocephalic, blonde, Aryan kindred. In treating of the question of selection he passes in review the bearing that religious opinions have had among different races in determining various degrees of consanguinity which were to be recognized as natural barriers against intermarriage among relatives. Considered generally, M. de Lapouge's article is a protest against futile attempts in the assumed name of philanthrophy to raise inferior types at the expense of those whom history from its earliest dawn has shown us to have been the leaders and pioneers in every path of human progress.—In a note on the recurrence among the Provençals of the present day of the myth of Ibicus, M. le Dr. Bérenger-Férand draws attention to the numerous characteristics derived from Hellenic antiquity which are still to be met with on the site of ancient Greek settlements. The modern tale of the detection of a murder through a reference by the murderers themselves to the birds which had been near the spot where the deed was done, is current both at Toulon and La Grasse. Both versions agree closely with the Greek original as to the course of the events, although the myth had been accepted as a true account of a contemporaneous occurrence in the latter place many years before it received its modern names of persons and places from the Toulonais.—In a note on the history of anthropology in 1788, M. Topinard has collected together various interesting details as to the precise meaning attached at that and earlier periods of the last century to the terms anthropology and ethnology. A doubt exists, however, as to the latter term, which is generally believed to have originated in its present sense with W. Edwards, when in 1839 he founded his so-called Ethnological Society. Dr. Topinard derives many curious facts from the manuscript work of Chavannes, Professor of Theology at Lausanne, whose speculative views as given in his writings he believes to have largely influenced the Encyclopædists no less than the author of "Emile."—Report by Dr. P. Topinard on the Neolithic skull, found at Feigneux (Oise) in 1887, which presents undoubted traces of having been trepanned both during life and after death.

SOCIETIES AND ACADEMIES.

London.

Royal Society, May 31.—"Colour Photometry. Part II. The Measurement of Reflected Colours." By Captain W. de W. Abney, R.E., F.R.S., and Major-General Festing, R.E., F.R.S.

In a previous paper we showed how the luminosity of different spectrum colours might be measured, and in the present paper we give a method of measuring the light of the spectrum reflected from coloured bodies such as pigments in terms of the light of the spectrum reflected from a white surface. To effect this the first named of us devised a modification of our previous apparatus. Nearly in contact with the collimating lens was placed a double image prism of Iceland spar, by which means two spectra were thrown on the focussing screen of the camera (which was arranged as described in the Bakerian lecture for 1886), each formed of the light which enters the slit. The light was thus identical in both spectra. The two spectra were separated by about $\frac{1}{8}$ of an inch when the adjustments were complete. A slit cut in a card was passed through this spectrum to isolate any particular portion which might be required. The rays coming from the uppermost spectrum were reflected by means of a small right-angled prism in a direction nearly at right angles to the original direction on to another right-angled prism. Both prisms were attached to the card. From this last prism the rays fell on a lens, and formed on a white screen an image of the face of the spectroscope prism in monochromatic light. The ray of the same wave-length as that reflected from the upper spectrum passed through the lower half of the slit, and falling on another lens formed another image of the face of the prism, superposed over the first image. A rod placed in front of the screen thus cast two shadows, one illuminated by monochromatic rays from the top spectrum, and the other by those from the bottom spectrum. The illumination of the two shadows was equalized by means of rotating sectors which could be closed and opened at pleasure during the time of rotation. The angle to which the sector required to be opened to establish equality of illumination of the two shadows gave the ratio of the brightness of the two spectra. When proper adjustment had been made, the relative brightness was the same throughout the entire spectrum.

To measure the intensity of any ray reflected from a pigment, a paper was coated with it and placed adjacent to a white surface, and it was so arranged that one shadow of the rod fell on the coloured surface and the other on the white surface. The illuminations were then equalized by the sectors, and the relative intensities of the two reflected rays calculated. This was repeated throughout the spectrum. Vermilion, emerald-green, French ultramarine were first measured by the above method, and then sectors of these colours prepared, which when rotated gave a gray matching a gray obtained by rotation of black and white. The luminosity curves of these three colours were then calculated and reduced proportionally to the angle that each sector occupied in the disk. The luminosity curve of the white was then reduced in a similar manner, and it was found that the sum of the luminosities of the three colours almost exactly equalled that of the white. The same measurements were gone through with pale-yellow chrome and a French blue, which formed a gray on rotation, with like results. It was further found that *the sum of the intensities* of vermilion, blue, and green varied at different parts of the spectrum, and the line joining them was not parallel to the straight line which represented white for all colours of the spectrum and which itself was parallel to the base. Since a straight line parallel to the base indicated degraded white, it followed that if the intensity of the rays of the spectrum were reduced proportionally to the height of the ordinates above a line tangential to the curved line (which represented the sum of the intensities of the three colours at the different parts of the spectrum) and were recombined, a gray should result. A method was devised of trying this, and the experiment proved that such was the case. The same plan enabled the colour of any pigment to be reproduced from the spectrum on the screen. The combination of colours to form a gray on rotation by a colour-blind person was also tried, and after the curve of luminosity of the colours had been calculated and reduced according to the amount required in the disk, it was found that the sum of the areas of the curves was approximately equal to the white necessary to be added to a black disk to form a gray of equal intensity as perceived by him. The spectrum intensity of gas-light in comparison with the electric light was also measured, and the amount of the different colours necessary to form a gray in this light was ascertained by experiment.

As before, it was found that the calculated luminosity of the colours was equal to the white which, combined with black, formed a gray of equal luminosity.

The question of the coloured light reflected from different metals was next considered, and the method of measuring it devised, as was also the method of measuring absorption spectra. The luminosity curves obtained by the old method were compared with those obtained by the present method, and so close an agreement between them was found to exist as to give a further confirmation that our former plan was accurate. A number of pigments that can be used for forming grays by rotation were measured, and the results tabulated in percentages of the spectrum of white light and on a wave-length scale.

Physical Society, June 9.—Prof. Reinold, President, in the chair.—The following papers were read:—On the analogy between dilute solutions and gases as regards Gay-Lussac's and Boyle's and Avogadro's laws, by Prof. van 't Hoff, presented by Prof. Ramsay, F.R.S. If a dilute aqueous solution of sugar (say 1 per cent.) be placed in a vessel, A (the walls of which are permeable to water, but not to sugar molecules), and immersed in a large quantity of water, B, water will pass from B to A until a certain difference of pressure exists between the inside and outside of A, that difference depending on the temperature and concentration of the solution. The pressure is called *osmotic pressure*, and the walls of A are said to be *semi-permeable*. Such a vessel may be artificially produced by depositing ferrocyanide of copper on unglazed porcelain; but many of the experiments dealt with in the paper have been made with the cells of plants, the walls of which form good *semi-permeable membranes*. At constant temperature the osmotic pressure is found to be proportional to the concentration of the solution, and for a given concentration the pressure is proportional to the absolute temperature. Similar results have been obtained with solutions of KNO_3, K_2SO_4, NaCl, &c., and Soret has found that if a solution be heated unequally at different parts, the warmer parts are less concentrated, just as in gases under similar conditions the warmer parts are more rarefied. The numerical results are in fair accordance with those deduced from the laws above stated. Theoretical proofs of the laws are given, in which reversible cycles and the second law of thermodynamics are made use of. By similar reasoning the author concludes that "under equal osmotic pressure, and at the same temperature, equal volumes of all solutions contain the same number of molecules, and moreover the same number of molecules which would be contained in a gas under the same conditions of temperature and pressure." These results are confirmed by Pfeffer's direct determinations of osmotic pressure, and Raoult's experiments on the "molecular lowering of vapour-pressure," and the "molecular depression of the freezing-point of the solvent." The latter part of the paper contains applications to chemical phenomena. Prof. Rücker regretted that the names Boyle's law and Gay-Lussac's law had been so persistently made use of in the paper, as he thought a wrong impression would be spread as to the nature of the phenomena. He also considered it probable that the proportionality observed was merely the result of the smallness of the ranges over which the experiments had been made. Mr. H. Crompton took exception to the imaginative character of the reasoning, and thought much more experimental proof was required before the results could be accepted for any but very small ranges of concentration. In answer to Prof. Reinold, Prof. Ramsay said the experimental data were not obtained by van 't Hoff himself, but were taken chiefly from Raoult's determinations.—On a method of comparing very unequal capacities, by Dr. A. H. Fison. One coating of each condenser is joined to earth, and to one end, A, of a high resistance (20,000 or 30,000 ohms), through which a current is flowing. The small condenser is charged to the P.D. existing between the ends A, B, of the resistance, and discharged into the large one. This is repeated a great number of times. If C be a point between A and B, the resistance between A and C may be varied until the P.D. between them is equal to that between the coatings of the condensers after n operations. If the insulated coatings be now joined to C through a galvanometer, no deflection will result. The relation between the capacities C_1 and C_2 of the large and small condensers is given by

$$\left(1 + \frac{C_2}{C_1}\right)^n = \frac{R_{AB}}{R_{BC}},$$

where R_{AB}, R_{BC} are the resistances between AB and BC respectively. Since time is required to perform the operation, the instantaneous capacities cannot be compared, and accordingly the measurements are taken after a definite time of electrification. A special rotating key was shown for performing ten operations per revolution, in which a trigger arrangement was provided for stopping the rotation after a predetermined integral number of revolutions. The method has been used for comparing a small air-condenser with a microfarad. The capacity of the former was also calculated electro-statically (correction being made for the edges), and that of the latter measured electro-magnetically by a ballistic galvanometer. The results give a value for v equal to $2{\cdot}965 \times 10^{10}$. In these experiments the capacity of the rotating key was allowed for. Under favourable conditions, capacities in the ratio of 1 to 1000 or 1 to 10,000 can be compared with an accuracy of $\frac{1}{4}$ per cent. Prof. Ayrton thought the novelty of the arrangement was in the rotating key, as the method of comparing unequal capacities by charging the smaller and discharging it into the larger a considerable number of times had been described and used by himself and Prof. Perry in their experiments on the specific inductive capacity of gases. —Mr. W. Lant Carpenter exhibited a new form of lantern, recently constructed by Mr. Hughes, of Dalston. The mahogany body is hexagonal, and each of the three front sides is provided with condensers and projecting arrangements. The back side opens to give access to the radiant, which in this case is a Brockie-Pell arc lamp, but if necessary a lime-light can be readily substituted. The lamp is fixed to the base-board, and the body can be rotated through 60° on either side of the central position, thus allowing any of the three nozzles to be directed towards the screen. The three sets of condensers are placed so that their axes intersect at a point about which the radiant is placed. The centre nozzle is fitted as a lantern microscope, with alum cell and various sets of condensing lenses and objectives, and a space in front of the main condensers is provided for polarizing apparatus. The focussing arrangement consists of a skew rack and pinion and a fine screw adjustment, and the whole microscope can be easily removed and a table polariscope substituted. The right-hand nozzle is arranged for the projection of ordinary lantern-slides, and the left-hand one is provided with an adjustable slit for spectrum work. A small table sliding on rails serves to carry the prisms, and the same rails support projecting lenses. Prof. S. P. Thompson congratulated Mr. Lant Carpenter on his selection of the Brockie-Pell lamp as the radiant, for, in addition to its being a focussing-lamp, it is unique in the fact that it works satisfactorily on either constant current or constant potential circuits.—Note on some additions to the Kew magnetometer, by Prof. Thorpe, F.R.S., and Prof. Rücker, F.R.S. In their magnetic survey of Great Britain and Ireland the authors have experienced considerable difficulty in making the necessary adjustments of the small transit-mirror used for determining the geographical N. point from observations on the sun. To make the required adjustments it is necessary to obtain an image of the cross-wires reflected from the mirror; and owing to the large amount of extraneous light, and the insufficient illumination of the cross-wire, the image is difficult to see. To exclude extraneous light, a tube is placed between the transit-mirror and the telescope, and a small screen placed behind the mirror. The cross-wires are illuminated by light reflected from a small platinum mirror introduced between the eye-piece and the cross-wires, which are viewed through a hole in its centre. The mirror is placed at 45° to the axis, and reflects a considerable quantity of light on the cross-wires when directed towards a bright part of the sky. In some cases it is advisable to take observations of the sun without first adjusting the transit-mirror, and afterwards correct the error introduced thereby. To do this a finely-divided scale is placed in the plane of the cross-wires, and from the position of the image, as indicated on the scale, the correction can be made. Observations taken with the mirror in adjustment and others taken when out of adjustment, and subsequently corrected, give very concordant results. The Rev. Father Perry said the improvements described were of great importance, for difficulties similar to those experienced by the authors had caused him to abandon the Kew magnetometer for field work, and to use a theodolite instead.

Linnean Society, June 21.—Mr. F. Crisp in the chair.—Mr. F. W. Oliver exhibited the aquatic and terrestrial forms of *Trapella sinensis*, of which he gave a detailed account, illustrated by diagrams.—Dr. R. C. A. Prior exhibited a branch of the so-called "Cornish elm," and described its peculiar mode of growth, which suggested its recognition as a distinct species. In the opinion of botanists present, however, it was regarded as merely a well-marked variety of the common elm.—On behalf of Mr. R. Newstead, of the Grosvenor Museum, Chester, photographs and drawings of the little grebe, *Podiceps minor*, were exhibited to illustrate a peculiarity observed in the mechanism of the leg-bones.—Mr. A. W. Bennett exhibited under the microscope, and made remarks upon, filaments of *Sphæroplea annulina* (from Kew), containing fertilized oospores.—Mr. Thomas Christy exhibited specimens of natural and manufactured Kola nuts, and explained how the latter might always be detected.—The following papers were then read:—Dr. P. H. Carpenter, on the *Comatulæ* of the Mergui Archipelago.—Prof. P. Martin Duncan and W. P. Sladen on the *Echinoidea* of the Mergui Archipelago.—Mr. W. P. Sladen, on the *Asteroidea* of the Mergui Archipelago.—Mr. W. Bolus, on South African *Orchideæ*.—Mr. R. A. Rolfe, a morphological and systematic revision of *Apostasiæ*.

Geological Society, June 7.—Dr. W. T. Blanford, F.R.S. President, in the chair.—The following communications were read:—A letter from H.M. Secretary of State for India, accompanying some specimens of rubies in the matrix from Burma.—On the Sudbury copper deposits (Canada), by J. H. Collins.—Notes on some of the auriferous tracts of Mysore Province, Southern India, by George Attwood.—On the Durham salt-district, by E. Wilson. In this paper the author described the new salt-field in the North of England, occupying the low-lying country bordering the estuary of the Tees, and situated partly in Yorkshire and partly in Durham. The history of the rise and progress of the salt-industry in South Durham was given, since the first discovery of salt by Messrs. Bolckow, Vaughan, and Co., at Middlesborough, in the year 1859. The stratigraphical position of the saliferous rocks of the Durham salt-district was considered in some detail. The diverse views which have been previously expressed on this head were referred to, and reasons given for concluding that all the beds of rock-salt which have been hitherto proved in this field, and the red rocks with which they are associated, belong to the upper portion of the Trias, viz. to the Upper Keuper series (Waterstones subdivision). The probable area of this salt-field, the limits of the distribution, and varying depths of the chief bed of rock-salt were indicated, and the extent of its supplies pointed out. In conclusion, the author called attention to the waste, as well as to certain other disadvantages resulting from the process of winning the salt now in operation.—On the occurrence of *Calcisphæræ*, Williamson, in the Carboniferous Limestone of Gloucestershire, by E. Wethered.—Second note on the movement of scree-material, by C. Davison; communicated by Prof. T. G. Bonney, F.R.S.

Anthropological Institute, May 29.—Francis Galton, F.R.S., President, in the chair.—A paper by Mr. G. H. Kinahan was read, on rubbings from ancient inscribed stone monuments in Ireland.—Dr. Stewart gave an account of the inhabitants of Paraguay.

June 12.—The Rev. H. G. Tomkins read a paper on Mr. Flinders Petrie's collection of ethnographic types from the monuments of Egypt. The author classified the collection under the four heads of Westerns, Southerns, Asiatics, and Egyptians; and examined, in order, the races mentioned under each of these heads. Among the Westerns are the Tahennu, or fair people, who, as Egyptian mercenary troops, founded, by a prætorian revolt, the famous twenty-second dynasty, to which Shishak, the invader of Palestine, belonged. The Lebu, or Libyans, fall under this head; and the author identifies with them the light-complexioned, fair-haired, and blue-eyed brickmakers of the celebrated tomb of Rekhmara. The want of the long side-locks is not surprising, since they were slaves employed in the lowest drudgery. The Shardina furnished highly-trained soldiers to the Egyptian army of Rameses II. They wore helmets with two horns, crested with a disk, and seem to have been Sardinians. Under the head of Southerns we have very various and interesting types. It is curious to find, in the paintings, blacks with red hair; but it seems probable that the colour was produced by the use of dye. Mr. Tomkins gave a full description of the race of Pûn, and dwelt particularly upon the terraced mountains covered with incense-trees that caused so much astonishment to the officers of Queen Hatasu. He also gave a probable explanation of the origin of the remarkable features of Amenhotep IV., the celebrated Khu-en-aten, whose mother, Queen Tua, was distinguished for her beauty.

Mathematical Society, June 14.—Sir J. Cockle, F.R.S., President, in the chair.—The Vice-Chancellor of Cambridge University (Dr. C. Taylor), read a paper on the determination of the circular points at infinity.—Prof. M. J. M. Hill followed with a paper on the c- and p-discriminants of integrable differential equations of the first order.—Mr. Tucker (Hon. Sec.), communicated papers by Lord Rayleigh, Sec. R.S., on point-, line-, and plane-sources of sound.—Note on rationalization, by H. Fortey.—Applications of elliptic functions to the theory of twisted quartics, by Prof. G. B. Mathews.—Prof. Greenhill, F.R.S., communicated remarks on coefficients of induction and capacity and allied problems, in continuation of a former paper (January 1879).—The following were taken as read: electrical oscillations, by Prof. J. J. Thomson, F.R.S.; and demonstration of the theorem "that the equation $x^3 + y^3 + z^3 = 0$ cannot be solved in integers," by J. R. Holt.

Zoological Society, June 5.—Dr. Edward Hamilton, Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of May.—Mr. H. E. Dresser exhibited a specimen of a new Shrike from the Transcaspian district of Central Asia, which he proposed to name *Lanius raddei*, after Dr. Radde, of Tiflis, its discoverer.—Mr. Sclater, on the part of Mr. F. M. Campbell, exhibited a pair of Pallas's Sand-Grouse (*Syrrhaptes paradoxus*), shot in Hertfordshire in May last, and made remarks on the recent immigration of this Central Asiatic bird into Western Europe.—The Secretary exhibited, on behalf of Prof. R. Collett, a nest, eggs, and two young ones in down of the Ivory Gull (*Larus eburneus*), belonging to the Tromsö Museum, which had been obtained in Spitzbergen in August 1887.—Mr. Warren communicated a paper on Lepidoptera collected by Major Yerbury in Western India in 1886–87, forming a continuation and completion of two previous papers by Mr. A. G. Butler on Lepidoptera collected by the same gentleman in similar localities. The present collection contained examples of over 200 species of Heterocera, of which about one-fourth were described as new. Mr. Warren remarked upon the abnormal development of separate organs, such as the antennæ and palpi, in tropical insects, as being rather specific aberrations from a generic type, than as warranting the erection of new genera.—A communication was read from Mr. Martin Jacoby, containing descriptions of some new species of Phytophagous Coleoptera from Kiukiang, China.—Mr. F. E. Beddard read some notes on the structure of a peculiar sternal gland found in *Didelphys dimidiata*.—Mr. G. A. Boulenger read a paper on the scaling of the reproduced tail in Lizards, and pointed out that the scaling of the renewed tails of Lizards may, in some cases, afford a clue to the affinities of genera or species to one another.—Mr. F. E. Beddard gave a preliminary notice of an apparently new form of Gregarine, found parasitic on an earthworm o the genus *Perichæta* from New Zealand.

CAMBRIDGE.

Philosophical Society, May 21.—Mr. J. W. Clark, President, in the chair.—On solution and crystallization, by Prof. Liveing. When a substance passes from a state of solution into the solid state, the new arrangement of the matter must be such that the entropy of the system is a maximum; and, other things being the same, the surface energy of the newly formed solid must be a minimum. If the surface tension be positive, that is tend to contract the surface, the surface energy will be a minimum when the approximation of the molecules of the surface is a maximum. The essential difference between a solid and a fluid is that the molecules of the former maintain approximately the same relative places, whereas the molecules of a fluid are subject to diffusion. Further, crystalloids in assuming the solid form assume a regular arrangement of their molecules throughout their mass, which we can usually recognize by the optical properties of the crystal, and by the cleavage. If we suppose space to be divided into equal cubes by three sets of parallel planes, each set at right angles to the other two, and suppose a molecule to be placed in every point where three planes intersect, we shall have an arrangement which corresponds with the isotropic character of a crystal of the cubic system. But of all the surfaces which can be drawn through the system the planes bounding the cubes meet the greatest number of molecules, those parallel to the faces of the dodecahedron meet the next greatest number of molecules, and those parallel to the faces of the octahedron meet the next greatest number. Also if we take an angular point of one of the cubes as origin, and three edges of the cube as axes, and the length of an edge of the cube as the unit of length, every plane which cuts the three axes at distances p, q, r respectively from the origin, where p, q and r are whole numbers, will be a surface of maximum concentration of molecules, but the concentration will be less as p, q and r are greater. Hence forms which are bounded by these planes, which follow the law of indices of crystals, will be forms of minimum surface energy and therefore of equilibrium. The tendency in general will be for substances with such a structure as is here supposed to take the form of cubes, since the cube will have the greatest concentration of molecules per unit of surface. But the total surface energy will depend on the total surface as well as on the energy per unit of surface, and for a given volume the surface will be diminished if the edges and angles of the cube are truncated by faces of the dodecahedron and octahedron, or by more complicated forms. When a solid is broken, two new surfaces are formed each with its own surface energy, and the solid must be more easily fractured when the new surfaces have the minimum energy. Hence substances with the structure supposed must break most easily in directions parallel to the sides of the cube, dodecahedron and octahedron; and these are the cleavages observed in this system. If we suppose the molecules placed at the centres of the faces of the cubes, instead of at the angles, the arrangement will still be isotropic, but the octahedron will be bounded by the surfaces of greatest condensation, and the cube will come next to it. It is probable that substances which cleave most readily into cubes, such as rock-salt and galena, have the former structure, while those which have the octahedral cleavage may have the latter arrangement of their molecules. For the pyramidal and prismatic systems we may suppose space divided not into cubes but into rectangular parallelopipeds with edges equal severally to the axes of the crystals, and molecules placed as before. For the rhombohedral system we may suppose space divided into rhombohedra, or in crystals of the hexagonal type into right prisms with triangular bases, and for the other systems into parallelopipeds with edges parallel and equal to the axes. In each case if the molecules be disposed at points of intersection of three dividing planes we shall have such an arrangement as satifies the optical conditions, and planes which follow the law of indices are surfaces of maximum condensation. Calculations show that whenever a crystal has an easily obtained cleavage the direction of cleavage corresponds to the surface of greatest condensation, and that the most common forms of crystals correspond in general to forms of minimum surface energy. The surface tension of a plane surface will have no resultant out of that plane, but where two plane surfaces meet in an edge, or angle, the tensions will have a resultant of sensible magnitude in some direction falling within the angle. Whenever all the faces of a crystallographic form are developed, every such resultant will be met by an equal and opposite resultant, and the form will be one of equilibrium. If one edge, or angle, be modified, the opposite edge, or angle, must either be similarly modified, or the resultant arising from the modification must be equilibrated by some internal forces produced by displacement of the molecules. In general, equilibrium is attained by similar modifications of similar edges and angles, but when only some of the edges or angles of a crystal are modified, while other similar edges or angles are not modified, we usually have evidence of the consequent internal strain. Thus cubes of sodium chlorate, which have half the angles truncated by faces of a tetrahedron, rotate the plane of polarized light, hemihedral tourmalines are pyro-electric, and so on. This theory therefore accounts for the plane faces of crystals, the law of indices, the most common combinations, and the cleavages. The same theory accounts for the development of plane faces when a crystalline solid of any shape is slowly acted on by a solvent. Solution will proceed so long as the entropy of the system is increased by the change, but when the solution is nearly saturated there will be an increase of entropy from the solution of a surface which has more than the minimum surface energy, while there will be no increase from the solution of a surface which has only the minimum energy.—On the effect of an electric current on saturated solutions, by Mr. C. Chree, M.A. This paper contains an account of experiments whose aim was to determine what effect, if any, an electric current may have on the quantity of salt required to form a saturated solution. Strong currents and a rapidly reversing commutator were employed. Certain chlorides were dealt with, and in no case did the existence of a current produce any sensible immediate effect. When heating was allowed to take place, the action of the current appeared to check the solution that would naturally have followed. This view was further supported by experiments on the effects of simple heating. These experiments showed, however, that an originally saturated solution when slowly heated can dissolve salt only with extreme slowness.

PARIS.

Academy of Sciences, June 18.—M. Janssen, President, in the chair.—Lagrange's hypothesis on the origin of comets and meteorites, by M. H. Faye. According to the author's calculations, this hypothesis, first submitted to the Bureau of Longitudes in 1812, does not hold good for the comets whose orbits do not quite approach any of the planetary orbits. But it would seem capable of being applied to the meteorites, whose fragmentary character, minute size, chemical and mineralogical identity with the constituent elements of the earth, combined with their great abundance, would seem to be absolutely incompatible with an extra-planetary origin. The earth alone with its satellite best satisfies all the conditions of the problem, while its orbit is continually intersected by millions of these bodies, as required by the hypothesis in question. Hence their origin is to be sought in the earth itself and in the moon, whence they were ejected under conditions which have long ceased to exist.—Fluorescence of ferruginous lime, by M. Lecoq de Boisbaudran. These experiments show that a small quantity of the sesquioxide of iron added to the carbonate of lime produces a green fluorescence after high calcination in the air. This fluorescence, which is occasionally somewhat intense, is very sensitive to the action of heat; hence it soon fades away in the presence of the electrode, retaining its brilliancy only in the parts of the tube furthest removed from the centre of action.—Experimental researches on the diseases of the vine, by MM. Pierre Viala and L. Ravaz. Having already shown that the different reproductive organs found on the parts affected by black rot belong to the fungus, cause of this disease, the authors here demonstrate the true parasitic character of the fungus itself. They once for all establish the filiation which exists between its various forms of reproduction, and thus make it evident that the blight on the leaves has the same origin as that of the grapes.—Researches on the accidental errors occurring in the observations of transits made by the method of eye and ear, by M. G. Rayet. In supplement to the studies of Struve, Robinson, Dunkin, Finlay, and others, the author here describes the results of special observations made on about seventy stars, or constellations, comprised between 20° of austral declination and the North Pole. He has thus determined the numerical value of the accidental errors relative to some dozen stars between 80° and 89° 22'·3 of declination.—On the rings of Saturn, by M. Perrotin. During the opposition of Saturn in the present year the author has made a series of micrometric measurements of the rings by means of the great equatorial of the Observatory of Nice. The results of these observations, made for the purpose of determining the dimensions of the system, are here fully tabulated for the whole period from February 2 to May 8.—On the planet Mars, by M. Perrotin. On presenting the already promised sketches of recent appearances in this planet, the author remarked that since his last communication the region of Libya has undergone fresh modifications. The sea which covered the surface of this insular mass has mostly receded, its present appearance being intermediate between that of 1886 and its condition a few weeks ago. The existence has also been determined of canals or channels, partly double, running from near the equator to the neighbourhood of the North Pole. They mainly follow the meridian, and merge in the seas encircling the white snow-cap of the Pole, and, strange to say, their course may be followed across the seas themselves right up to the snow-cap.—Heat of combination of the primary, secondary, and tertiary aromatic monamines with the acids, by M. Léo Vignon. In continuation of M. Louguinine's study of the primary monamines, the author here investigates the reactions of several acids on a series of primary, secondary, and tertiary monamines. He deals more especially with aniline, monomethyl aniline, and dimethylaniline in the presence of the hydrochloric, sulphuric, and acetic acids.—On the decomposition of the ferrate of baryta at high temperatures, by MM. G. Rousseau and J. Bernheim. In his researches on ferric acid, Fremy has indicated the analogy existing between the ferrates and the manganates, as established by the wet process. Here the authors endeavour to ascertain whether the parallelism is maintained in the reactions of the dry process and in their mode of decomposition under the action of heat.—On some new double phosphates in the magnesian series, by M. L. Ouvrard. The products here described have been obtained by the method already referred to in a previous note on the action of the alkaline phosphates on the alkaline earthy oxides. All the metals investigated are allied in their composition to the substances obtained with the pyro- and ortho-phosphates of potassa and soda.—On the poison of the Hymenoptera with smooth sting, and on the existence of a poison-cell in the honey-producing insects, by M. G. Carlet. In continuation of his researches on the barbed sting of bees, wasps, &c., the author here studies the smooth sting of Philanthus, Pompilus, &c. He describes the nature of the poison, which has merely a soporiferous effect, and clearly determines the presence of a poison-cell in bees and allied insects.—On a new bacterial disease of the duck, by MM. Cornil and Toupet. An examination of the bacteria of this disease ("duck cholera") shows that it is quite distinct from chicken cholera. The virus is fatal to the duck alone, sparing hens and pigeons, and killing rabbits only when an excessive dose is administered.—M. A. d'Arsonval contributes an elaborate paper on the relation between animal electricity and surface tension.

AMSTERDAM.

Royal Academy of Sciences, May 26.—M. Franchimont, communicating the results of experiments on nitro-ureides and nitramines, said that internal ureides, by their behaviour with nitric acid, may be distinguished into at least three sorts.—M. Sahols treated of the calculation of the moments of flexion and the shearing-forces in railway-bridges, in connection with the irregular distribution of the pressures exercised by the axles of locomotive-engines. He pointed out what elements of the engine are of especial influence on these, and arrived at very simple approximative formulæ for the calculation of the said moments and forces on bridges of not too insignificant length.—M. Pekelharing read a paper on the proliferation of endothelium-cells in arteries, stating, as the result of his experiments made upon them, that this proliferation is most probably caused by a diminution of the pressure upon the inner wall of the arteries.—M. van der Waals treated of the connection between the change in the density of the limiting layer between fluid and vapour, and the mode of action of the molecular forces.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Proceedings of the Royal Society of Edinburgh, Sessions 1883 to 1887 (Edinburgh).—Transactions of the Royal Society of Edinburgh, vol. xxx. Part 4, vol. xxxii. Parts 2, 3, 4, vol. xxxiii. Parts 1, 2 (Williams and Norgate).—Transactions of the Royal Society of Edinburgh, vol. xxxi. Botany of Socotra: Prof. I. B. Balfour (Williams and Norgate).—British Reptiles and Batrachians: C. C. Hopley (Sonnenschein).—Anleitung zu Wissenschaftlichen Beobachtungen auf Reisen, Bands 1 and 2: Dr. G. Neumayer (Oppenheim, Berlin).—Mathematical Drawing Instruments, sixth edition: W. F. Stanley (Spon).—Proceedings of the American Association for the Advancement of Science, New York Meeting, 1887 (Salem).—British Dogs, Parts 17 to 20: H. Dalziel (U. Gill).—Observations made at the Hong Kong Observatory in the year 1887: W. Doberck (Hong Kong).—Synopsis of the Aphididæ of Minnesota: O. W. Oestlund (St. Paul).—Report on Botanical Work in Minnesota for the year 1886: J. C. Arthur (St. Paul).—Preliminary Description of the Peridotytes, Gabbros, Diabases, and Andesytes of Minnesota: M. E. Wadsworth (St. Paul).—Palæolithic Man in Eastern and Central North America (Cambridge, Mass.).—Journal of the Royal Microscopical Society, June (Williams and Norgate).—Proceedings of the Society for Psychical Research, June (Trübner).—Sulla Forza Elettromotrice del Selenio, Memoria del Prof. A. Righi (Padova).

CONTENTS.

THURSDAY, JULY 5, 1888.

THE DECADENCE OF THE CHEMICAL PROFESSION IN GOVERNMENT OPINION.

THE Professorship of Chemistry in the Royal Naval College, Greenwich, is, or is about to become, vacant through the resignation of Dr. H. Debus, F.R.S., and it is currently reported that the authorities have been advised to discontinue the professorship, and to substitute for it a mere lectureship or readership. We trust that this rumour may prove unfounded, or that the Government may be led in time to see the folly of degrading a subject which, if properly handled, is of such extreme value and importance to the Navy. We say degrade, because in the first place it cannot be questioned that chemistry is a science which may claim to rank with any other which enters into the curriculum at Greenwich, both on account of its educational value and its direct usefulness; and because any such change must of necessity tend to lower the value of chemical knowledge in comparison with that of other subjects in the eyes of the students.

It is scarcely necessary to point out in how many ways a knowledge of chemistry may be of service in the Navy. Our sailors are stationed in all parts of the world, and the question of water-supply both for men and boilers is an ever-present one: a decision as to the quality of a water can only be given after it has been examined chemically. Again, the action of sea-water on metals, the corrosion of metals, the decay of timber, the economical use of fuel, are all matters in which the sailor nowadays is deeply interested, and these can only be rightly understood by those who have acquired a sound knowledge of chemical principles. There are very many other ways in which chemistry is of direct value to the sailor; but, most important of all, there is no subject which, if properly and practically taught, affords the same opportunity of training the student to observe accurately and to think correctly, and it is especially on this ground that chemistry should be assigned a high position in the course at a Naval College. It will, however, not suffice to require attendance at a course of lectures in which general chemistry is treated of in slow and measured cadences and no heed is paid to the requirements of the students: the subject must be taught technically, and almost exclusively with direct reference to matters familiar to sailors and to their future requirements; and the training must be to a very large extent carried on in the laboratory, and not in the lecture-room.

If the results thus far obtained at Greenwich have not been such as to lead the authorities to appreciate the value of the subject, the most short-sighted course they can possibly pursue in the hope of obtaining better results in the future will be to assign a lower rank to chemistry. In cases of grave disease, if a practitioner, guided by particular traditions, and operating under conditions which he takes no particular pains to control, be unsuccessful, it is not usual to call in another of lower grade; but on the contrary, if possible, one of equal or higher grade is summoned, holding different and perhaps wider views, and the effort is made to improve the conditions so as to give every opportunity for his treatment to be successful: and so may it happen, we trust, at Greenwich.

In these anxious times of fierce competition the nation cannot afford that the Government should act so as in the least degree to diminish the importance of so valuable a branch of science as chemistry. Moreover, a golden opportunity will be lost if occasion be not now taken to appoint at Greenwich a chemist who not only is known to have been thoroughly trained, but who has given proof, by his own researches and those of his pupils, that he is possessed of enthusiasm, and capable of extending our knowledge. In connection with explosives, and in many other directions, there is infinite opportunity for research; and it is a disgrace to the nation that the Navy at present has not a single chemist of repute in its service, especially as such invaluable service has been rendered to the War Department by its chemist, Sir Frederick Abel.

If the professorship at Greenwich be quashed, it is unlikely that a man of proper calibre will be attracted by a mere lectureship; and thus another step will have been taken to indicate that in this country we care little for science, that our Government is blind to facts so clearly recognized by foreign Powers. Among the noted men of science now in the House of Commons, besides Prof. Stokes, there are three chemists, Prof. Maskelyne, Sir Lyon Playfair, and Sir Henry Roscoe: we feel sure that they will not allow the Government to make a false move in so important a matter without publicly warning them, and without fully eliciting their reasons.

THE LAND AND FRESH-WATER MOLLUSCA OF INDIA.

Land and Fresh-water Mollusca of India. Edited by Lieut.-Colonel H. H. Godwin-Austen, F.R.S., &c. Parts I. to VI. (London: Taylor and Francis, 1882–88.)

ALTHOUGH much has been done to elucidate the fauna of our great Eastern dependency, very much more still remains to be accomplished: vast tracts have yet to be explored scientifically, even though, year by year, new areas are visited by the naturalist and collector, and fresh species are added to the list.

This is especially evident in the case of land and fresh-water Mollusca; whilst so scattered are the various descriptions of the species up and down the pages of different scientific journals and magazines, that the specialist himself has a hard task to ascertain whether a given example is new or not.

It is true that Hanley and Theobald,[1] in their now classical work, went some way towards remedying this state of things; but their task was never completed, and many new forms have been discovered since their publication was brought to a close.

Under these circumstances the present undertaking cannot fail to be most welcome. It is modestly described as "supplementary" to the work just named; but, in reality, it is something far more important, if we may

[1] The names are inadvertently reversed on the title-page of Colonel Godwin-Austen's book.

judge from the six parts (257 pp.), which, with their sixty-two hand-coloured plates, will, when the index is issued, complete the first volume. Each species figured is most thoroughly described, and, when not new, full quotations with the synonymy are given. The figures are also the handiwork of Colonel Godwin-Austen, and though they by no means attain to that standard of excellence with which Sowerby at his best made us familiar, they are effective and (fortunately) under, rather than over, coloured. The illustrations of the living animals, which are copied from drawings by a native artist, are extremely spirited and life-like. Anatomical details where obtainable are given, and, what is yet more important from the systematic point of view, the Radulæ are figured; for, whatever may be the case with marine forms, in the Pulmonates certainly it is of the greatest importance.

How truly gigantic the task Colonel Godwin-Austen has set himself, becomes apparent when it is seen that, disregarding political boundaries, under "India" are included "South Arabia, Baluchistan, Afghanistan, Kashmir, Nepal, Burmah, Pegu, Tenasserim, Malay Peninsula, Ceylon, and other islands of the Indian Ocean"; whilst, when necessary for purposes of comparison, genera from yet other countries are also described and figured (*e.g. Geomalacus*, *Africarion*)—of a truth there does not seem to be any probability that the author will ever, like some scientific Alexander, be in want of fresh fields for conquest!

The weak point of the work appears to be that "the genera and sub-genera are treated of in no particular order, ... but as data concerning them can be put together and the drawings completed." Nothing, we feel sure, but the necessity of doing so, if the work was to be published at all, can have induced the author to adopt such a course. Few things are more provoking to the student than the necessity of turning to many different pages in the same work when engaged on a particular subject, an inconvenience which even a good index does not obviate; whilst in its absence matters are not improved by such a table as the one given on p. 253, which professes to be "a classification of families and genera treated of in the preceding pages," but which only includes those placed by the author in Fam. Zonitidæ (or, as it is misprinted, Zon*a*tidæ).

This infringement of Nature's first law renders it hard to disabuse one's mind of the unfortunate impression derived on a first examination that the author had transcribed and enlarged his preliminary notes without previously sorting them. Nor does the reason alleged seem altogether sufficient: "the classification can be hereafter attempted; we shall then be better able to judge what weight, generic or sub-generic, to give to the many genera now recorded from the Indian region." This did not preclude the author from giving—as we trust he will do in a future part—what all who try to follow him would find of great assistance; namely, a provisional table of classification in which the main divisions at all events should be shown.

Such a scheme would be none the less useful seeing that he evidently, like most authorities, has his own notions on the subject, which at present can only dimly be guessed at by a careful perusal of the text. Thus at p. 165 he speaks of "the two great natural divisions of land Mollusca, . . . the Helicidæ and Cyclophoridæ." Again, he agrees with Fischer (v. p. 59) that *Hyalimax* belongs to the same group as *Succinea*; but on pp. 64–65 gives a "key to genera of Limacidæ and Arionidæ" in which *Hyalimax* figures.

Another drawback, if it may be so described, is the undue prominence given to minor differences, and the consequent elevation into genera of what in the eyes of the general conchologist are sub-genera, or even mere sections of sub-genera. This, however, raises a very wide and much vexed question, into which far be it from us to enter.

In thus briefly indicating what appear to us the shortcomings of this important work, we are by no means blind to its great value, and we most heartily wish success to its author in his arduous undertaking, which bids fair to prove as endless as that of Sisyphus.

RECENT MATHEMATICAL BOOKS.

A Chapter in the Integral Calculus. By A. G. Greenhill, M.A. (London: Hodgson, 1888.)

A Treatise on Plane Trigonometry: containing an Account of Hyperbolic Functions, with Numerous Examples. By John Casey, F.R.S. (Dublin: Hodges, 1888.)

A Higher Arithmetic and Elementary Mensuration. By P. Goyen, Inspector of Schools, New Zealand. (London: Macmillan, 1888.)

The Harpur Euclid. Book II. By E. M. Langley, M.A., and W. S. Phillips, M.A. (London: Rivingtons, 1888.)

THE first book in this list is intended to be used by way of supplement to any ordinary treatise on the calculus. It might almost be said that Prof. Greenhill is nothing if not *hyperbolic*, for he expatiates in seas of these functions and the kindred Weierstrassians. No one has done better work than he in his endeavours to make them "familiar as household words" to students, to whom, as Dr. Casey remarks in the preface to his "Trigonometry," they are very interesting and important, not only in pure mathematics but also in mathematical physics. Our author, who is quite in accord with this opinion, considers that "the hyperbolic functions have not received adequate treatment in ordinary text-books; to illustrate this importance, a digression has been made on their principal properties, illustrated by examples of their application."

In the course of thirty-six pages he gives an exceedingly clear sketch, and works out in detail several examples, viz. the different forms of the result of $\int dx/(x-p)\sqrt{R}$, where $R \equiv ax^2 + 2bx + c$, and several kindred forms. The analogies and properties of the hyperbolic functions are considered; three sections are given up to hyperbolic trigonometry; three more to relations connecting true, excentric, and mean anomaly in an elliptic and hyperbolic orbit; and a section to Abel's theorem and the general integral $\int \frac{N}{D} \cdot \frac{dx}{\sqrt{R}}$, and to the rectification of some curves.

There is a large collection of examples, and the whole pamphlet is "teres atque rotundus."

Dr. Casey's "Treatise on Plane Trigonometry" is quite independent of the "Elementary Trigonometry" by the same author. It is a most comprehensive work, and quite as exhaustive as any ordinary student will require. Dr. Casey shows his usual mastery of detail, due to thorough acquaintance, from long teaching, with all the *cruces* of the subject. He has embraced in his pages all the usual topics, and has introduced several points of extreme interest from the best foreign text-books. A very rigid proof is given of the exponential theorem, and a section is devoted to interpolation. Dr. Casey approves of, but does not at present venture to adopt, the practice of French authors who use log sin A instead of our old friend L sin A, *i.e.* he would prefer $\bar{1}\cdot859$ to $9\cdot859$.

Chapters V. and VI., which are devoted to triangles and quadrilaterals, are exceedingly interesting, and contain quite a crop of elegant propositions culled from many fields. Following the course adopted by other recent writers, he gives a systematic account of imaginary angles and hyperbolic functions. "The latter are very interesting, and their great and increasing importance, not only in pure mathematics but in mathematical physics, makes it essential that the student should become acquainted with them." We may remark that Dr. Casey adopts the following notation: sh, ch, th, coth, sech, cosech, for sinh, cosh, &c.; and has gone further than his English predecessors in introducing at this early stage the angle τ, Hoüel's *hyperbolic amplitude of* θ (τ = amh. θ). Numerous illustrative examples and tables afford practice to the student in this branch.

The modern geometry has a small niche, and here we note, as one of several small clerical errors come across, in addition to the list furnished, that (440) should have *cosecants* in place of *secants*. The special results, which on Dr. Casey's useful plan are numbered consecutively, reach 810. The book is rich in examples, and will be sure to find for itself a place on the mathematician's shelves within easy reach of his hand.

The object of the author of "A Higher Arithmetic and Elementary Mensuration" is to furnish a work suited to "the senior classes of schools, and candidates preparing for public examinations." A large number of typical exercises are worked out, and the student, being left to observe and think for himself, acquires, or should acquire, a sound practical knowledge of the subject, which the author rightly thinks will be more abiding than the knowledge of rules and definitions obtained by the mere committal of them to memory. For the benefit of beginners, in many of the examples the steps of the reasoning are given at some length, but the student is advised, as he grasps the details, to shorten the work as much as possible in the examples he subsequently works out. The text covers all the ordinary divisions under which arithmetic is discussed in the books, even our old friend alligation having a chapter assigned to it. The last two chapters are devoted to the mensuration of plane surfaces and of solids. There are 400 exercises at the end, in addition to a very great number scattered throughout the book. The whole is a vast storehouse of well-put matter, which should render a reader quite independent of any other text-book, and, we might say, of a teacher.

Book II. of "The Harpur Euclid" is on the lines laid down in the edition of Book I., and the subject is handled in an interesting manner. There is a sufficient number of good illustrative examples, with assistance enough to enable a thoughtful boy to work them out by himself. We are glad to see a few examples on antiparallels and symmedians. These lines must soon force their way to a foremost position even in a school curriculum. This is a useful and handy edition brought out in accordance with the Syllabus of the Association for the Improvement of Geometrical Teaching.

THE BOTANY OF THE AFGHAN DELIMITATION COMMISSION.

The Botany of the Afghan Delimitation Commission. By J. E. T. Aitchison, M.D., F.R.S., Naturalist attached to the Mission. Being Trans. Linn. Soc., Ser. 2, Bot. v. 3, pp. 1–139, tt. 1–48; with two Maps. (1888.)

OF this expedition Dr. Aitchison has already published, in the *Pharmaceutical Journal and Transactions*, Ser. 3, v. 17 (1887), a report on the drugs, and he is preparing a report on the zoology to appear in the Transactions of the Linnean Society.

In several previous collections and papers relating to the Punjab flora ("Flora of Jhelum," "Lahul, its Flora and Vegetable Products," "Flora of Hushiapore," "Hand-book of Trade Products of Leh"), and especially in his Report on the plants of the Kuram Valley, Dr. Aitchison had shown himself an excellent collector and an enthusiastic botanist; and by the knowledge of the Afghan flora he had acquired in this preceding work he was eminently qualified to make the most of the opportunities afforded on hasty marches and in rough camps. The Secretary of State for India, who employed Dr. Aitchison on this duty, may certainly be well satisfied with the present botanic section of the Report. In 28 quarto pages Dr. Aitchison describes the country traversed, and the general character of the vegetation, interspersed with many economic and agricultural remarks. The remainder of the Report consists of a list of the plants collected in order, with descriptions of the new species, most of which are figured. There are about 800 plants catalogued, whereof 53 are new to science. The whole forms a most valuable addition to our scientific knowledge of an interesting frontier region. Dr. Aitchison started from Quetta on September 22, 1884, and proceeding west struck the Helmund on October 19; following the course of the Helmund and Harut, he was close to Herat on November 4; the remaining nine months, up to September 1885, he was in Khorassan and Badghis, *i.e.* in North Cabul.

The dry region of South-West Asia extends into Western India—into Sind, the Punjab, Rajputana; but in his "Flora of British India," Sir J. D. Hooker accepts the political frontier of India as his western limit. It is impossible in local floras to find natural boundaries. Beluchistan and Cabul are thus excluded from the "Flora of British India." They are included in Boissier's "Flora Orientalis"; but Boissier had by no means plentiful material for this frontier. The additions now made by Dr. Aitchison are not to be estimated by the 53 new species alone, but by the further light thrown on numerous little-known species, and especially by the quantity of economic information collected.

Of the 800 plants enumerated, the richest orders are Leguminosæ with 78 species, Compositæ with 77 species, Gramina with 63 species, Cruciferæ with 57 species, Chenopods with 38 species. The large Umbelliferæ allied to Asafœtida are finely illustrated in plates 18 to 29; four new species are described. There remain still many points about these valuable gum-producing plants of Central Asia that are obscure. Of the 78 Leguminosæ, no less than 37 are of the genus Astragalus, and of these 13 are new. Of the petaloid Monocotyledons the most prominent are the Iridaceæ (2 new species of Iris), and the Liliaceæ (26 species, of which 3 are new).

The introductory narrative, with the lists of characteristic plants at different levels and localities, enables a phytographic botanist to apprehend the nature of the country and climate. Cabul is clearly a much richer country agriculturally than has been hitherto supposed. Corn can be cultivated without irrigation either above 3500 feet altitude, or in the vicinity of a river; and a large area between these levels is capable of irrigation. The dry and hot summer is, as was before well known, very favourable to the production of fruit, and it now appears almost equally so to the production of vegetables. Dr. Aitchison found "not uncommon," in clefts of rocks and escarpments of hill-sides, the common fig (*Ficus Carica*, Linn.), apparently wild; and collected both male and female branches, some of the male receptacles containing both male and gall flowers. Dr. Aitchison had few opportunities of examining the country above 5000 feet; at the spots he did visit he found a very scanty flora, and above 7000 feet absolute sterility.

Dr. Aitchison compared his collection in the Kew Herbarium, and had the assistance of Mr. W. B. Hemsley in the technical botanic work, and in arranging the plates; and the new species described are given as of "Aitchison and Hemsley," except a few Liliaceæ, &c., attributed to "Aitchison and Baker." By this plan Dr. Aitchison gives to botanists who cannot refer to the specimens a guarantee that the new species are "good," and that the list of names has been accurately worked out. It is indeed the closeness with which a list of the present kind is worked out that gives it more than a temporary value.

Praise is due to Dr. Murie, the Assistant Secretary of the Linnean Society, for the style in which this number of the Society's Transactions has been put out. Credit may certainly be given to the India Office for assisting in a publication of this class; somebody there must have discovered that the money spent by the old Company on Roxburgh and Buchanan-Hamilton, on Royle and on Wallich, was not money spent on ornamental books, but has been returned, many times over, to the Government coffers.

OUR BOOK SHELF.

The Principles of Agricultural Practice as an Instructional Subject. By John Wrightson, Professor of Agriculture and Principal of the College of Agriculture, Downton. (London: Chapman and Hall, 1888.)

THIS is a useful text-book, written in an interesting style, and by one who shows that in addition to being scientific he is thoroughly practical. The subject-matter of the book was first delivered as lectures to science teachers, and it deals with the duties of teachers as well as the defects of students under examination. It exposes in commendable language the narrow grooves into which agricultural teaching under the Science and Art Department has fallen. This is called "molecular and microscopic" in place of "bold and comprehensive," which ought to be the suitable form of description if the Department were properly constituted.

The book is the first of a series of text-books. It disposes in a clear and unmistakable manner of many knotty points of difficulty to the farmer and to the student, in matters relating to the nature and composition of soils, kinds and qualities of manures—"artificial and natural," "general and special,"—also to the cultivation of soil, and the growth and rotation of crops. Under these various headings many popular fallacies are exposed, connected with the classification of soils, the action of lime and nitrate of soda when applied to soil, the value of silica and of farm-yard manure, the sources of the supply of nitrogen to the growing plant, and the supposed ultimate exhaustion of soil—called a "store-house, a laboratory, a vehicle"—by systems of cropping.

The merits and methods of "autumn-cleaning" are duly introduced. The valuable work of the Rothamsted experiments is fully acknowledged and concisely explained.

This new contribution to agricultural literature comes at an appropriate season, when there is a growing demand for text-books of a trustworthy kind: so few can be found which are not simply the incoherent drivel of men who have but a very limited and imperfect knowledge of the subject.

The work is written in a style which will lead the student to think for himself, and but for one serious blunder in the later pages we should have pronounced it to be exceptionally perfect. Partial toleration is extended to the practice of sowing down land to pasture with seeds swept from the stable-loft. The loss sustained by the country through Miss Ormerod's warble-fly is thrown into the shade by the loss which has resulted from this exploded system of seeding down to grass. We hope to see the error corrected in a second edition, which, judging from the value of the book, cannot be long in making its appearance.

A Season in Sutherland. By J. E. Edwards-Moss. (London: Macmillan, 1888.)

THIS is a pleasant little book, though it affords no kind of information to the naturalist or to the sportsman, while it can hardly pretend to rank as a contribution to *belles lettres*. But Mr. Edwards-Moss is acquainted with certain districts in the north of Sutherlandshire; he has thrown a fly, and shouldered a breechloader; and he writes of his experiences in an unpretentious and graceful way which ought to commend the little volume as an accompaniment to an after-dinner cigar. He also quotes freely from contemporary and other authorities, including amongst these that profound thinker and teacher, Mr. Mallock. Mr. Mallock, as quoted by Mr. Edwards-Moss, tells us that we should "learn to love the sea, and the woods," and also "the wild smell of the heather"; from which we may gather that Mr. Mallock has probably discovered some portion of the country in which the heather smells of patchouli.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Sky-coloured Clouds" at Night.

IN NATURE, June 28 (p. 196), Mr. Backhouse notes the appearance of illuminated clouds to northward at night. Similar clouds are seen from here on almost every clear night near the summer solstice. For the last two years special note has been taken of them. In 1887 they were first seen at midnight on June 13, and last seen on July 20; this year their first appearance at midnight was on June 4, and they are still visible every clear night. The clouds are not, as far as I have observed, coloured, but shine with a pearly or silvery lustre. I have seen them at midnight as high as 30° altitude, but they are generally confined to the first 10° or so above the northern horizon. The facts that they vary greatly from night to night in appearance, being sometimes almost absent, and that one or two photographs that have been taken of them show them simply as ordinary cirrus clouds, all seem to indicate that they really are very high cirrus lighted by the sun.

I may add that the upper glows continue to be seen here, though with varying intensity, on every clear night both before sunrise and after sunset, but for the past year no reddish ring or glare has been observed round the sun in the day-time.

Ben Nevis Observatory, July 2. R. T. OMOND.

Micromillimetre.

THE Council and the Fellows in general meeting have taken into consideration the objection raised by Prof. Rücker to the term micromillimetre.

This term was in use by microscopists long before the British Association Committee formulated their system of nomenclature; but nevertheless the Society are unwilling, on a question of precedence only, to insist upon retaining a word which may give rise to confusion.

The Council have therefore directed the editors of the Journal to discontinue the use of the term "micromillimetre," and to substitute for it that of "micron," which has been in use for as long a time as the former word.

This resolution has been confirmed by a general meeting of the Society, who agree with the Council in thinking that the term "micromētre," proposed by Prof. Rücker, would give rise to considerable confusion from its similarity to "micrometer."

FRANK CRISP, Secretary.

Royal Microscopical Society, June 21.

A Prognostic of Thunder.

AMONG prognostics of thunder given in books and elsewhere I have never met with mention of what has for years been to me one of the most trustworthy of weather signs, viz. the formation of *parallel streaks or bars*, definite in form but limited in number, extent, and persistence, appearing chiefly in cirrus and cirro-stratus, but also on the surface (apparently) of nimbus. In cirrus they give often almost the first intimation of coming change after settled weather, and are almost, if not quite, invariably followed within twenty four or thirty-six hours by thunder. When they appear on nimbus the interval is much less, but they are not seen, I think, on the thunder-cloud itself. These small patches of definitely marked "parallel bars" are to be distinguished from the more general parallel arrangement which is often seen on a much larger scale, but which has not, so far as my observation goes, any very distinct value as a weather prognostic.

As the thundery season is now on, it would be interesting to have the observation confirmed by others, and the connection of this particular form of cloud with electric disturbance explained. I have no doubt of the fact, and have often, and several times within the present year, pointed out these "parallel bars" to friends who had never observed them, and hardly ever has my prediction of thunder failed to come true. In the very few cases in which thunder has not followed in the same locality, I think I may say that there have never been wanting instances of its occurrence within a moderate distance. B. WOODD-SMITH.

Branch Hill Lodge, Hampstead Heath, June 29.

Parasites of the Hessian Fly.

ALTHOUGH numbers of these most useful insects were bred last year from puparia of 1886 and 1887, there seemed to be a good deal of doubt among some entomologists as to whether the American species, *Merisus destructor*, had occurred. I bred a large number of various kinds, four of which appeared to me to agree in every respect as to form, colour, and marking with the description given by Prof. Riley.

During the present month (June) I have bred a very large number of this parasite, specimens of which (both male and female) I sent to Dr. Charles Lindeman, of Moscow, who has just replied that "the specimens of parasites sent, bred in England from the Hessian fly, seem to me to be *Merisus destructor* of Riley, &c." He thus fully confirms my opinion of last year, that the American parasite had occurred here. Early in the spring I bred several other parasites which, I am much inclined to think are *Platygaster herrickii* of Riley; and, if this is correct, it strengthens the opinion that part of the attack came from America.

The damp muggy weather appears to be decidedly favourable for the development of "the pest," the larvæ of which I found at the beginning of this week engaged in weakening the stems of barley; and on June 2 I observed a female Hessian fly ovipositing. The number of eggs laid was 158! Truly a most prolific "pest," requiring both natural and artificial means to check its increase. F. E. S.

Fact and Fiction.

As Mr. Grant Allen reads NATURE,—indeed this is evident from a sentence in his novel "This Mortal Coil," now in course of publication in *Chambers' Journal*—he will perhaps be good enough to satisfy my doubts upon the following practical points in electro- and thermo-physics. Firstly, in order to successfully attract a flash of lightning to a tree, is it necessary to bury beneath its roots a Rhumkorf coil? Secondly, do Rhumkorf coils exist which are *without* secondary wires? Thirdly, will an electric discharge ignite commercial petroleum oil?

While it is not undesirable that scientific fact should be imported into modern fiction, it is surely important that it should be fact: loose statements are apt to perpetuate themselves.

Mr. Allen is exceptionally well read and observant, and I am quite at a loss to understand why a simple solution of continuity in that part of his copper conducting wire which was immersed in the petroleum would not as well have served his purpose (if indeed, that purpose could have been effected in the way described), as the elaborate expedient of burying and destroying an expensive piece of apparatus.

Dublin, July. HARRY NAPIER DRAPER.

The Nephridia of Earthworms.

THE number of NATURE published on June 28 last contains (p. 197) an interesting paper by Prof. Baldwin Spencer, which deals with the excretory system of the gigantic Australian earthworm *Megascolides*. Prof. Spencer promises an extended memoir upon the anatomy of this earthworm, which has not hitherto received more attention than a superficial description. In the meantime the paper in NATURE contains an abstract of the results obtained by the author from his investigation of the nephridia.

This paper is particularly interesting to myself, as I am at present preparing an account of some further investigations into the anatomy of the excretory system of earthworms, which will supplement those already published by me in the *Quart. Journ. Micr. Sci.* (January 1888).

It appears from Prof. Spencer's paper that, as he himself points out, there is a considerable resemblance between the excretory organs of *Megascolides* and of *Perichæta aspergillum*, one of the species investigated by me; there are at the same time certain important differences between the two types.

In my paper upon *P. aspergillum* I described only the nephridia of the anterior segments of the body. I have since found that the nephridia of the posterior segments are in some respects different. In both cases, however, the external orifices are more numerous than I was at first inclined to suspect. They are not limited to the area of the segments which lie between the setæ, but are found all over the body, scattered irregularly; *they have, in fact, no relation whatever to the segmentation of the body.*

The tufts of tubules in the posterior segments of the body are not so abundantly developed as in the anterior segments, where they not only form a layer covering the body-wall and septa but occupy nearly the whole of the cœlomic space available.

Again, *they are furnished with numerous ciliated funnels*; I have not detected them in the nephridia of the anterior segments, but they have been possibly overlooked. These funnels are very abundant; for example, I counted five in one section on one side of the body. Some of them are distinctly larger than others; the larger ones were occasionally observed to be connected with a duct which perforated the septum and joined the nephridia of the segment behind.

In the posterior segments there is a distinct tendency for the nephridial system to become broken up into isolated clumps. It by no means always happened that this tendency to segregation was in relation to the metamerism of the body. On the contrary, the tufts are scattered irregularly in the segments; and the intersegmental septa do not always isolate the nephridial tufts which are connected by intraseptal tubules.

In fact the nephridial system of *Perichæta* and *Megascolides* forms a strong support for that view of the origin of the segmented from the unsegmented worms that has been so ably argued by Arnold Lang.

With regard to the ciliated funnels of *Perichæta*, it is right to mention that they have been already observed by Dr. Benham in a species from Luzon, though no description has been published. Prof. Spencer has made the observation that in the posterior region of the body of *Megascolides* there are a pair of much larger nephridia, which are furnished with a ciliated funnel opening into the segment in front of that containing the nephridium. He believes that these have arisen from the smaller nephridial tufts, and that from them are derived the paired nephridia of such earthworms as *Lumbricus*. I am quite disposed to agree with Prof. Spencer with regard to these points. I had already made some observations upon another earthworm which exhibits a closely analogous structure.

In *Perichæta aspergillum*, as I have mentioned above, some of the ciliated funnels are larger than the others, and are connected with a nephridial tuft lying in the segment behind that which contains the funnels. I could not, however, notice a very marked difference in the size of the nephridial tubules themselves.

In another species of *Perichæta*, viz. *P. armata*, which was characterized some years ago (*Ann. Mag. Nat. Hist*, 1883) by myself, the nephridial system is rather different from that of *P. aspergillum*. Mr. W. L. Sclater, of the Calcutta Museum, has kindly sent me some specimens of this worm which were well preserved. The worm has been lately re-described by Dr. D. Rosa (*Ann. Mus. Civ. Genova*, 1888), who states that each segment contains a pair of nephridia, opening internally by a funnel which lies in the segment anterior to that which contains the nephridium. So far Dr. Rosa's description is accurate, but there are also innumerable tufts of minute tubules which may or may not be provided with funnels. *These appear to be for the most part quite distinct from the large pair of nephridia.* The calibre of the tubules of the large nephridia is many times greater than that of the small tufts. The latter open by numerous orifices on to the exterior.

In the present state of our knowledge it appears to me permissible to derive the paired nephridia of *Lumbricus*, &c., from the network of *Perichæta* in two ways, which may both have actually taken place:—

(1) By the gradual development of a pair of large nephridia, in the way suggested by Prof. Spencer, out of the minute nephridial network, and the gradual disappearance of the latter (which is in the process of disappearance in *Perichæta armata*).

(2) By the gradual breaking up of the nephridial network into tufts of tubules specially connected with the setæ, as in *Acanthodrilus multiporus*, and by the disappearance of all but two of these. Dr. Benham's interesting form, *Brachydrilus*, which has two pairs of nephridia in each segment, offers an intermediate condition in this reduction.

To assume that the ordinary condition of the nephridial system of earthworms has been derived in these two ways, renders the mutual affinities of certain earthworms easier to understand. For example, *Perionyx* (which is so nearly allied to *Perichæta* in most respects, but differs in having nephridia of the *Lumbricus* pattern) may have been derived from *Perichæta* directly *via* some such form as *P. armata* without having passed through an "*Acanthodrilus* stage"; again, *Deinodrilus*, which is intermediate in many characters between *Perichæta* and *Acanthodrilus*, is also, as I shall hope to show later, intermediate in the arrangement of its nephridia, and may therefore represent a stage in the evolution of *Acanthodrilus*.

Zoological Gardens, N.W. FRANK E. BEDDARD.

THE "AVOCET" ROCK.

THE circumstances attending the loss of the s.s. *Avocet* and *Teddington* towards the southern end of the Red Sea in the year 1887, and the subsequent finding of the small coral patch on which it is probable they both struck, are of interest, and deserving of record as showing the necessity for very close examination of seas where corals flourish, and the difficulties experienced in finding a small patch at a distance from land, when neither discoloration nor break of sea aid the searcher. It should be premised that the area between the Zebayir Islands and Jebel Zukur, in which this rock lies, had never been properly sounded, only a few scattered depths having been obtained. It is crossed yearly by hundreds of steam-ships—the majority of them British—and has always been accounted as deep, safe water.

On the 4th of March the *Avocet* was steaming southwards—with another steamer, the *St. Oswald*, with which she had kept company for some hours, not far from her—a strong head-wind and heavy short sea prevailing at the time. At about 8 a.m. a shock was felt, succeeded by two others, and shortly afterwards water was found to be coming in. It being evident that the ship would go down, the *St. Oswald* was signalled, and after a little time the crew of the *Avocet* were taken off by her, and the latter sank. A Court was held at Aden, and the evidence taken before it showed that the shock had been slight, one witness stating that he thought something had gone wrong in the engine-room; and another, that it was a heavy sea that had struck the ship. The verdict was that the ship had struck on an unknown rock in latitude 14° 21′ N., longitude 42° 38′ E., the position given by the master. No evidence was given to prove this position; but the fact of the *St. Oswald* being in company, and of other steam-vessels passing on either side of the two ships both just before and just after the accident, seemed to show that they must have been in the straight track, and that the position was not far wrong in longitude at any rate. H.M. surveying-ship *Flying Fish*, arriving at Aden shortly after the inquiry, spent some days on the suspected ground, and found nothing but deep water, over a hundred fathoms being found in the position given.

Those who have the responsibility of the issue of charts for the guidance of navigators may be pardoned if they are extremely sceptical and difficult to convince in the matter of new rocks in the great highways of traffic. So many instances occur of reports which on investigation prove to be erroneous—sometimes in the whole, sometimes in part (as of the position, for instance)—that very good evidence is required before a report, which seems in itself improbable, can be accepted, and one of Her Majesty's ships sent—perhaps from a long distance, and from other important duties—to spend many days in a search. In this case there was no doubt of the ship having foundered; but the cause of the disaster was somewhat doubtful, and her position was unsubstantiated. It was evident, however, that if she had struck bottom it must be a very small rock, as the presence of other vessels prevented the supposition of a wrong course.

The *Avocet* was partly laden with railway iron, she was pitching in a heavy sea, and the evidence of external injury was not convincing. Altogether it seemed more probable that some of this heavy material had fetched way and injured the ship from inside than that a rock could exist in the very track of the heavy trade of the Red Sea. The Admiralty therefore announced that they would order no further search until these points were cleared up, and the Board of Trade consented to order a further inquiry.

The witnesses were collected, and the Court sat on June 10, but before any further proceedings could take place a telegram was placed in the hands of the President announcing that the s.s. *Teddington* had foundered after striking an unknown rock 5 miles north-east of the *Avocet's* rock, or in latitude 14° 23′ N., longitude 42° 42′ 30″ E. This seemed sufficient, and the Court dissolved without any attempt to cross-examine the *Avocet's* officers on her position. The Admiralty telegraphed for a ship of war to proceed from Aden to examine the spot. The *Griffon*, therefore—whose captain had sat on the Court held there, and had concurred in the finding that the *Teddington* had struck on an unknown rock—spent over a week in traversing the area including both positions, sounding and dragging a chain cable suspended from her quarters, but found no sign of shallow water or rock. On her return to Aden, a fisherman announced that he knew the rock, and the *Griffon* returned with him, only to find that his rock was a well-known one 40 miles from the spot required.

Any further action was then suspended until the full report of the *Teddington* disaster was received. The official report of the Court held at Aden was long before it arrived in England, though the protest of the master was received before many weeks.

This stated that the *Teddington* was on her way north, and on June 9, at 6 a.m., she passed 5¼ miles eastward of Abu Ail, where she got a good position and the error of her compass, and thence steered to pass 5 miles east of the position given for the *Avocet* danger; calm, and weather fine. At 8.30 she struck heavily, nothing being seen under the stern, and no land in sight. Course was at once steered to the south-west, into the track of steamers, when the s.s. *Cairo* was met with, and the crew taken off, the *Teddington* foundering shortly afterwards. The master gave his position as in latitude 14° 24′ 30″ N., longitude 42° 42′ 30″ E., or 1½ mile north of the telegraphed position; but cause was afterwards seen to prefer the latter.

A statement was shortly after received from another ship that they passed the *Teddington*, abandoned and low in the water, at a time four hours later than that given for her foundering. This contradiction seemed to require explanation.

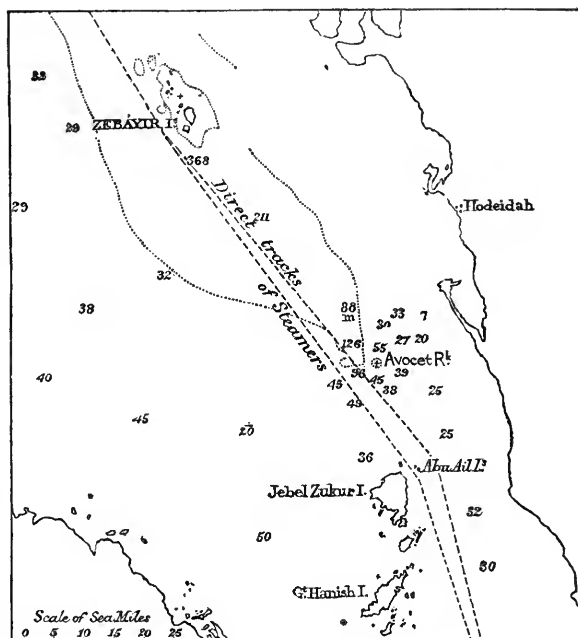
Before the official report arrived, the master of the *Teddington* called at the Admiralty by desire on August 4, and gave his account by word of mouth. His relation was so straightforward, and it was so evident on cross-examination that the ship had been navigated with great care, that it was clear that another and closer search must be made. Captain Free explained that the *Teddington* had been lost sight of in the haze, as the *Cairo* steamed away; and that it was believed she had then sunk.

The position now given, being 5 miles from the straight track that steamers usually endeavour to follow, gave much more probability to the existence of a rock than the *Avocet's* report, which placed it exactly in that direct route. Orders were therefore at once sent to H.M. surveying-vessel *Sylvia*—then in the Mediterranean—to proceed to the spot, and institute a minute search early in October, when the climatic conditions are most favourable to that work.

In September a reply was received to inquiries made of the master of the *St. Oswald* as to the position of his ship when signalled by the *Avocet*. This showed that the *St. Oswald* had found, when Jebel Zukur was sighted, that she was considerably to the eastward of the correct course, and that the position given by the *Avocet* was some four miles in error. The position now given was 14° 21′ N., 42° 41′ E., placing the *Avocet* within 1½ mile of the *Teddington's* danger. This greatly strengthened the evidence, and showed that a general strong cross-set must have existed on the morning that the *Avocet* was lost, sweeping the whole trade to the eastwards.

Unfortunate occurrences delayed the *Sylvia*, and when she arrived on the scene, the strong southerly winds had already set in. Nevertheless, a close search was accomplished, especially of the ground embracing the two best positions of the *Avocet* and *Teddington*, and extending far on either side. Six weeks were spent in this search, but no danger nor considerable shoaling of the water could be found. The heavy sea which caused her to part her cable, carry away anchor stocks, and do other damage, and also placed considerable difficulties in the way of marking the area with beacons, seemed also to afford a means of sighting the rock—had it existed—by the break that would probably be seen on it. When, however, the chart of the search was received, it was noticed that in one spot, nearly midway between the *Avocet* and *Teddington* positions, there was a slight shoaling of the water; a small area of 28 and 30 fathoms existing among the general depths of 35 fathoms. The *Sylvia* had anchored on this, and had commenced to search it carefully with the boats, but the freshening gale drove her from her anchors before the whole area was examined.

The indication afforded by this area, the slope of the sides of which was only a few degrees, was very slight,



but it was evidently necessary to re-examine it before it could be certainly stated that no small danger existed. H.M. surveying-vessel *Stork* was therefore directed to make a fourth search on her way to the East Indies.

Steering out from the mainland to the eastward, the *Stork* struck a depth of 28 fathoms at 8 a.m., April 25; but passing over it, the spot was not again found until late in the afternoon. The ship was then anchored with a light anchor in 26 fathoms of water, and the boats began to search. Just before dusk 6 fathoms was found. The night was luckily fine, and next morning the search was renewed, concluding in finding—not 100 yards from the ship—a small coral mound on which in one spot was a depth of only 15 feet at low-water summer level of the sea. Before, however, the examination was quite complete, the wind suddenly freshened, causing the ship's anchor to drag, and the ship to drift directly towards the rock. To clear this the cable had to be slipped, and the *Stork* thus narrowly escaped passing over the rock that she had just found.

The position of the rock is in latitude 14° 22′ 8″ S., longitude 42° 41′ 32″ E., 18 miles from the island of Jebel Zukur, and the same from the eastern shore of the sea, and out of sight of land except in clear weather, when Jebel Zukur is visible. The dangerous portion of the rock is only about 40 yards in diameter, but the soundings round for about 100 yards give indications of its presence.

Its slope is not so very steep as in some other instances of coral banks in this sea. Assuming that coral after it attains within a certain distance of the surface grows mainly outwards, and that the almost perpendicular sides of some of the Red Sea reefs are mainly the result of such outward growth, the comparatively gentle slope of the *Avocet* rock may be taken to show that it is in an early stage of its development; a view which its small size also supports.

The rock lies on the bank of soundings on the eastern side of the deep-water gully up the centre of the Red Sea, near its edge, and close to the point where it comes to an end. It has frequently been noticed that coral patches most readily form on the edges of such steep submarine slopes—witness other parts of the Red Sea itself—but they generally take the form of a scattered line along such an edge, and it is not usual for one small and isolated patch to alone make its appearance.

This rock is nearly midway between the *St. Oswald's* position for the *Avocet* and the telegraphed position of the *Teddington*, and is about 350 yards from where the *Sylvia* was at one time anchored. It lies about 5½ miles off the direct line between the Abu Ail channel and a point 3 miles west of the Zebayir Islands—the course generally taken by ships.

Seeing that transverse currents are by no means rare in the Red Sea, and also that many vessels—especially when bound north at night—habitually pass outside Abu Ail, it is a cause for marvel that no ship has ever struck this small danger before. One of the telegraph cables passes close to it—so close that it is doubtful on which side it lies, and the ship laying it may therefore be considered to have had a narrow escape. On the very morning of the *Avocet's* loss, a large troopship passed *east* of that vessel an hour before she struck. Evidence is already forthcoming of many ships having been swept to the eastward at different times, so that they must have passed very close to the *Avocet* rock.

The absence of a marked break on the rock is another somewhat curious fact, and shows how a short heavy sea without the accompaniment of an ocean swell can pass over as little water as 15 feet without showing more than the white horses which crown every wave when the wind is strong.

MAGNETIC STRAINS.

It has long been known that when an iron rod is magnetized its length is in general slightly increased. This phenomenon was first studied by Joule about the year 1847, and most of his experimental results have been confirmed by other physicists, among whom may be mentioned the names of Tyndall, Mayer, and Barrett.

Joule enunciated the law that the elongation of a magnetized rod is proportional to the square of its magnetization, a law which seems to have been pretty clearly supported by his experiments so far as they went. Now, when iron is subjected to the action of continually increasing magnetizing force, a point is at length reached when further increase of the force produces comparatively little effect upon the magnetization. The iron is then, in popular language, said to be "saturated," and is (or until lately was) commonly supposed to have attained a condition of magnetic constancy, so that none of the properties of the metal connected in any way with its magnetism would be materially affected by any increase of magnetizing force, however great, beyond what was necessary to produce saturation.

Joule carried many of his observations up to the so-called "saturation point," and then, perhaps naturally, seems to have assumed that nothing would be gained by going any further, and accordingly discontinued his experiments. It is, however, a somewhat remarkable fact that although his interesting discovery was soon widely known, an account of it appearing in almost every text-book dealing with electricity, while an exhibition of the phenomenon in question became a familiar lecture illustration, yet for the thirty-seven years following the publication of Joule's paper it seems never to have occurred to any experimenter to try what would be the effect of subjecting an iron rod to stronger magnetizing forces than those applied by Joule himself. Perhaps I may be pardoned if I refer to the accidental circumstance which led me to do so.

In 1884, a reprint of Joule's scientific papers was issued by the Physical Society, and I then read, for the first time, his original memoir on the effects of magnetism upon the dimensions of iron and steel bars. I had recently been engaged in an investigation of the heat-expansion of sulphur, changes in the length of rods of that substance being indicated by their action upon a small movable mirror which reflected the focussed image of a wire upon a distant scale; and it struck me that a similar method would be well adapted for the exhibition of magnetic expansions. Wishing to have the satisfaction of witnessing some of these effects, I put together a rough apparatus, in which the mirror principle was applied. The battery employed consisted of five large bichromate cells, the zinc plates of which were immersed in the solution by the action of a treadle, and withdrawn by an opposing spring when the pressure on the treadle was removed. The circuit included the magnetizing coil, a galvanometer, and a contact-key.

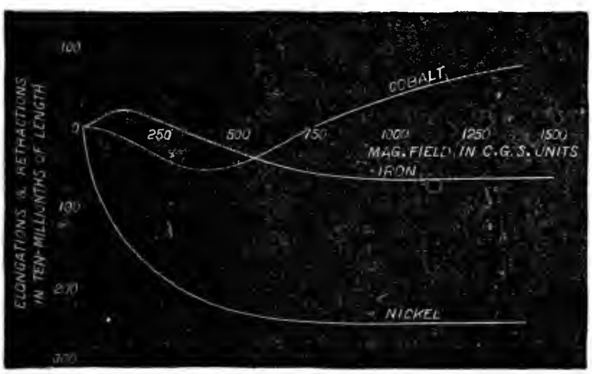
The first results of experiments made with this apparatus were disappointing. Everything appeared to be quite right: the mirror worked perfectly, as was shown by its deflection when the temperature of the iron rod was slightly varied; the iron was well annealed, and there could be no doubt that the magnetizing force used was more than sufficient to "saturate" it (in the popular sense). Yet the elongation indicated when the circuit was closed was only a small fraction of what had been expected, the movement of the focussed index upon the scale being, indeed, scarcely perceptible.

The arrangement was varied in several details, and further attempts were made, but without any better success. In these perplexing circumstances I happened to remove my foot from the battery treadle while the contact key was still depressed, and at the moment of doing so I noticed a curious "waggle" of the focussed image. A movement of the same kind was found upon trial to occur if the zincs were lowered into the liquid while the key was down. The operation was then performed very slowly, and the exact nature of the waggle became clearly revealed. As soon as the zinc plates touched the surface of the liquid the index immediately jumped into a position indicating a certain small elongation of the magnetized rod. As the zincs went in deeper, this elongation at first steadily increased, but only up to a certain point, after which it was *diminished*; and when they were completely immersed in the liquid, the focussed index had returned nearly to the zero position, showing that the elongation had almost entirely disappeared. When the zincs were again slowly raised, the same cycle of changes occurred in inverse order.

The conclusion obviously suggested by these observations was one that could not be readily accepted. It appeared as if the magnetizing force which had been used in the first instance was *too great* to produce Joule's effect, and that it was only when the current was diminished by increasing the resistance of the battery that the elongation of the iron became well developed. This view clearly involved the assumption that the common notions as to magnetic saturation must be at least in part erroneous, and I therefore endeavoured to find some other explanation of the apparent anomaly. In particular, I suspected that it might be due to electro-magnetic action of the kind known as "solenoidal suction" between the iron rod and the coil; but a few careful experiments convinced me that, although this might well have been the case, yet in fact it was not so. Nor did any other hypothesis present itself which would bear examination, and I accordingly fell back upon the first and natural interpretation of the facts, which implies that magnetizing force may exert an important molecular influence upon iron even when its magnetism is saturated.

A fuller investigation of the phenomenon was then made with very delicate apparatus and greater battery power, and the results were communicated during the next year to the Royal Society, the principal conclusion arrived at, so far as regards iron, being the following: When an iron rod is subjected to a continually increasing magnetizing force, its length at first increases to a maximum and then diminishes, ultimately becoming actually *less* than when the rod is unmagnetized.

I have since published accounts of further experiments, and amongst others of a series in which iron rings



surrounded by magnetizing coils were used instead of straight rods. The changes produced by magnetization in the diameter of the rings were of exactly the same nature, showing conclusively that the effects before observed could not have been due to any unexplained action of the ends of the rods.

By the kindness of Mr. W. H. Preece, F.R.S., who placed at my disposal the large secondary battery used in lighting his house at Wimbledon, I have recently been able to repeat some of my experiments with magnetic fields of exceedingly high intensity. Rods of iron, nickel, and cobalt were thus tested, and the results are clearly shown in the accompanying curves, where the abscissæ represent the magnetic fields due to the coil in C.G.S. units, and the ordinates the elongations and retractions of the rods in ten-millionths of their lengths.

The retraction of iron, it will be seen, becomes ultimately greater in amount than its maximum elongation, and reaches a limit in a field of 1000 or 1100 units, after which its curve becomes sensibly parallel to the horizontal axis. Nickel, unlike iron, retracts[1] from the very commencement, rapidly at first and afterwards more slowly, until in fields of 800 units and upwards its length becomes apparently constant. Cobalt behaves in a very remarkable manner. While the field is comparatively weak, no sensible change in either direction can be detected. After about 50 units of magnetizing force, the rod begins to contract, attaining its minimum length with 300 or 400 units. But instead of remaining unchanged in fields stronger than this, it again becomes longer. At 750 it regains its original length, and thence up to 1400, the highest field reached in the experiment, it continues to elongate steadily.

[1] The retraction of nickel under magnetization was first observed by Prof. Barrett (NATURE, xxvi. 585).

It should be understood that so far as mere details are concerned the curves in the diagram relate only to particular specimens of the metals in question. With different rods there will be certain small variations, dependent upon the purity of the metals and their physical condition. But I have always found that under increasing magnetizing force iron is at first extended and then contracted, nickel is contracted from the beginning, while cobalt is first contracted and afterwards extended.

My best thanks are due to Mr. Preece, not only for having given me the opportunity of carrying out the experiments described above, but also for the exceedingly kind and cordial manner in which he did so.

SHELFORD BIDWELL.

A METEOROLOGIST AT THE ROYAL ACADEMY.

ARTISTS and poets are supposed to draw their inspirations from communing with Nature; but it is well known that painters in oil are rarely successful with the cloud portion of their pictures.

For some reason or other, skies and clouds are always far more satisfactory in the water-colour exhibitions than in galleries devoted to oils. The transparency of the former medium enables a painter to put an amount of detail into his clouds which would make the sky far too heavy if attempted in oil; so there is no doubt that oil as a medium is peculiarly unsuitable for the reproduction of cloud-forms, and that the utmost skill is required to give even passable results.

Painters generally do pretty well when they only try to represent shading of the sky, or what Mr. Lockyer has called the zoning of colour in the heavens. They can paint the blue sky overhead gradually getting whiter and grayer as you approach the horizon, or the red round the horizon at sunset surmounted by a zone of orange shading through green into the blue above, as only shade and colour have to be rendered. But when artists try to delineate the form, and, still more, the texture, of clouds, the difficulties are so great that few painters attain excellence in this branch of their work.

Few have yet learnt that, putting the difficulties of the medium aside, the structure of a cloud has an anatomy as definite as that of a man; and that the perspective of cloud-forms obeys the same laws as that of bodies on the earth's surface. Everybody paints ordinary objects so as to show a characteristic texture or structure: the silk dress, the woollen carpet, the wooden floor, are all carefully distinguished; but how many realize the essentially different structure of cloud-forms—the hairy cirrus, the lovely fleecy sky, or the rocky masses of cumulus? Nobody would dare to draw a building, a road, or a tree out of its due perspective; but many seem to think that the forms and distances of the sky can be rendered by daubing white and blue and gray promiscuously over the canvas.

The chapters on clouds in Mr. Ruskin's "Modern Painters" sin against every canon of literature. They are disjointed, discursive, irrelevant, and wander into many by-paths; for one note brings in the causes of the failure of the Reformation in Germany, and the whole ends with a commentary on the nineteenth Psalm. But, in spite of all this, they preach in brilliant and poetic language the two great truths that clouds have distinctive characteristic structures, and that their perspective must be as carefully drawn as that of a building. In one of the illustrations—that of the tower of Beauvais Cathedral in front of a thundery sky—is the finest delineation of cloud in line that has yet been produced; and though Mr. Ruskin's writings have had a powerful influence on contemporary art in England, the following notes on the pictures now hanging on the walls of the Royal Academy will show that much still remains to be done before British artists have exhausted the possibilities of cloud-painting.

The great landscape of the year is undoubtedly Sir J. Millais' "Murthly Moss" (No. 292), and readers will naturally ask, Is the sky good? The answer is, unequivocally, Yes. Our great artist has selected a somewhat rare form of sky, but one which is most useful in giving distance and perspective to a picture. As a whole, the sky is covered with a sheet of thin flat cloud; but, while the top of the picture appears uniform, the sky lower down looks as if it were composed, or made up, of parallel bars, which get thinner and thinner as they approach the horizon.

If a series of disks stretched in a line from nearly overhead to the horizon, at a uniform height of about 10,000 feet, we should see the whole under-surface of those overhead; and progressively less and less, till on the horizon the thin edges of the disks only were visible, like straight bars. This is exactly what happens in Nature when a thin flat sheet of cloud is broken into irregular flakes. Above, there is only visible the flat, formless under-surface, while in the distance the thin edges of the flakes appear more and more like bars. Thus the picture of the sky alone gives instinctively the idea of retreating distance.

Turner, curiously enough, hardly ever painted cumulus, but almost always a coarser form of this flaky sky growing into thinner and thinner bars towards the horizon; and I have seen pictures by Mr. Leader, in which the same device was used for giving distance, with great effect. In Millais' picture the artist has painted the sky with consummate skill, true to Nature, and true to art in not destroying the balance of relative distance.

Another important landscape is No. 102, Mr. G. Boughton's "A Golden Afternoon." But in this the sky is scarcely satisfactory. The clouds are rather spotty, but yet not of the kind which come in flocks of little cloudlets; and it is difficult to make out either the precise form which it is intended to delineate, or the perspective of the whole sky. The reproduction of representative structure is simply nowhere, for at a distance neither form nor structure are discoverable; while close at hand the brush-marks are so apparent that the lower clouds appear to have a fibrous structure. This would be practically impossible, for though the summit of a rocky cumulus is often combed out into hairy cirrus, the rest of the cloud remains firm, and this would not occur on "a golden afternoon."

Mr. Leader can be complimented on sending three first-rate skies in the three pictures which he contributes to the exhibition. In No. 408 he not only paints "An Old English Homestead," but also a truly English sky. A wisp of cirrus floats over a well-painted cumulus, while the ideas of relative height and distance are well given. Cloud forms are essentially the same all over the world, but the details differ; and if the sky in this picture were alone, I could say that it was nowhere in the tropics, but somewhere in a temperate zone. In No. 638, "A Summer Day"—

> "When the south wind congregates in crowds
> The floating mountains of the silver clouds"—

Mr. Leader again paints the same kind of sky very beautifully; but in No. 421, over "The Sands of Aberdovey," he gives a totally different type of cloud. Here the clouds float as a thin white fleece on the sky, with some small raggy, evaporating cloud of a totally different structure at a lower level. The effect is very striking, and the accurate drawing of the forms gives height and distance to the picture.

Mr. V. Cole's "The Pool of London" (No. 350) has been purchased under the Chantrey bequest. This is a large, fine picture, in which the artist has employed a device for giving distance that was sometimes used by Turner. A dark mass of cumulus cloud on either side of the sky leaves a sort of bright vault running down the centre, in which high white clouds lead the eye to the dome of St. Paul's in the distance. The painting of all the clouds, and the effect of their floating at different levels, are very good; but somehow the scale of distance in the picture is scarcely satisfactory. Artists are conventionally allowed to diminish the size of objects in the foreground, and to increase that of distant objects so as to improve the effect; but the modern eye, which is trained to the accurate projection of objects at different distances given by photography, knows that in this picture the ships in the foreground should be bigger, and the Cathedral dome smaller than they are here delineated.

"Then came the Autumn, all in yellow clad," is the poetic title of Mr. G. Lucas's picture (No. 342). A beautiful, finely-painted shower-cloud, in the shape of a rising, driving cumulus, gives such an idea of space and height that it is a pleasure to look at such a truthful transcript of Nature. This is one of the best skies in the exhibition.

Close by, and in great contrast to the above, but fortunately well skied, hangs a small landscape which contains a sky of the worst possible description. White and blue and gray are patched about the canvas promiscuously, regardless of form or drawing or perspective; and the artist seems to consider that any mixture of these colours represents a cloud-covered sky.

Artists do not often break a lance with men of science, but Mr. J. Brett has run a tilt against the astronomers and geologists. One of his pictures of this year is an ambitious subject—"The Earth's Shadow on the Sky: the Rising of the Dusk." A short time after sunset in fine weather, the shadow of the earth appears to rise from the eastern horizon, like the segment of a leaden-gray arch; but there is little to suggest this on Mr. Brett's canvas, though the general effect of the picture is very pleasing. A bright green sea fills up the foreground, then comes a line of gray mist in shadow, with blue hills above; while the zoning of a gilded sunset sky from red through orange to blue is very skilfully handled. But the low mist is more characteristic of sunrise than sunset; and the sky appears to us very bright to be opposite the sun. This artist also shows a well-painted shower-cloud in "A Heavy Squall off the Start Lighthouse," and a confused cumulus in a slightly finished work entitled "The Bristol Channel."

In "Nearing the Needles—Return of Fine Weather after a Gale," Mr. H. Moore exhibits a pretty picture, with a lovely sea and sunlit chalk cliff; but the clouds are not very well defined; and are rather soft for the rear of a gale. The Needles appear to lie to the east of the observer, while the sea and ships appear to be running from south-east. If this is so, the sky has far more the character of a north-west than of a south-east wind. Another of Mr. Moore's pictures—"A Breezy Day in the Channel"—brings into evidence the great difficulty of painting clouds carefully, and yet of maintaining the balance of the picture. Here the clouds—irregular cumulus—are very good in form, and beautifully painted; but this careful work makes them so heavy that they appear rather too near. An artist's scale of distance is to a certain extent a scale of distinctness; so that when clouds are painted in minute detail, it is very difficult not to make them appear too near. The same criticism applies to this painter's "Westward," where another beautiful sky, correct both in form and perspective, is a good deal too heavy.

The low, ill-defined cumulus in Mr. Hook's "Low-Tide Gleanings" are not more finished than the rest of the picture, but are correct both in form and drawing; and the same remarks apply to his work, "A Day for the Lighthouse."

"Thanet Cliffs in the Time of Peace," by Mr. S. Cooper, shows a good cumulus with cirrus overhead; but in Mr. C. Hunter's "Fishers of the North Sea" the cumulus cloud is not satisfactory.

Mists on a mountain, with a gray sky, are very well painted in Mr. Faed's "And with the Burden of Many Years," and make an effective background to a striking work of art; while in "The Approach to Bealloch-na-ba" Mr. H. Davis has delineated mountain mist with equally good effect.

Mr. P. Graham's "A Norfolk River" contains a very good showery sky, but the brush-marks give an appearance of fibrous structure which would not be in Nature; while his "Driven by the Wind" contains an effective mass of gray nimbus or rain-cloud.

Mr. W. Shaw paints a good misty yellow-tinted sky in his "Tide Race"; but the great mass of cumulus behind Sir F. Leighton's central figure of the "Captive Andromache" is not very satisfactory.

The sky in "The Old Water-Way," by T. Liddell, is good so far as form is concerned, but is painted so heavily that the clouds look like clods. Philologists say that the word cloud is really derived from clod, but artists should not express that idea in their works. There is a rainbow in this picture, so ill defined that it is difficult to make out the succession of tints; though I think the red is meant to be outside, which is correct.

Mr. R. Rouse's "Pasture-land in Kent" would be much more pleasing if the clouds were more carefully painted, and not so like patches on the sky. In No. 553, Mr. H. Wells is to be complimented on having painted rays diverging from the sun from exactly the proper kind of sky. These rays are rarely seen except through a peculiar, flat, broken cloud; but they are usually associated with a firmer, harder sky than is here depicted.

Lastly, Mr. C. Johnson paints the "Plain of Arundel" under two well-drawn layers of cloud; and Mr. J. MacWhirter has hit off with great skill and accuracy a flat, broken cloud, lit from below by a setting sun, beside the picturesque castle of "Edinburgh."

Such are some of the more notable skies in our great national exhibition of pictures, and it will be seen at once that the best skies are painted as a rule by those who have achieved the greatest success in the other elements which make up a good picture. May we not therefore fairly conclude that part of their success is due to their faithful rendering of skies and clouds; and that it behoves those who wish to attain a high place among landscape painters to study the form, the structure, and the perspective of those clouds which give life, and height, and distance, to every picture? RALPH ABERCROMBY.

THE OXFORD UNIVERSITY OBSERVATORY.

THE following are the principal parts of the Thirteenth Annual Report of the Savilian Professor of Astronomy to the Board of Visitors of the University Observatory, read June 6, 1888:—

I. *Lectures.*—In addition to the requisite statutable lectures, Prof. Pritchard has offered some others of a more elementary and quasi-public character on descriptive astronomy, and expressed as far as possible in untechnical language. He has been so much encouraged by the interest manifested in these lectures that he proposes to offer another and perhaps more extended series on the recent speculations as to the origin of the Cosmos from meteoric collision and on matters cognate therewith.

II. *Instruments.*—The De La Rue equatorial is in excellent order; its mechanical mounting is now equal to the delicate purposes of stellar parallax to which it has been uninterruptedly applied during the last twelve months. Although the mirror is perhaps somewhat dimmed with age, its figure, which has been recently tested by comparison with the presumed best productions of the day, retains its original very remarkable character.

The two mirrors mentioned in the last Report have been mounted temporarily on the large equatorial for the purpose of the comparison of their photographic action. An efficient electric control contrived by Sir H. Grubb has also been added with the view of securing the great accuracy necessary in the movement of the telescope. The work for which the mirrors were intended having been completed, they have now been dismounted.

Dr. De La Rue having provided the funds necessary for a photographic telescope of 13 inches aperture and of the pattern suggested at the Paris Conference of 1887, the large equatorial has been sent to Sir H. Grubb at Dublin, for the purpose of attaching thereto the instrument in question, and of carrying out the other considerable alterations necessary for the photographic charting of the heavens, as proposed at the aforesaid Conference.

The transit-circle is in perfect order.

III. *Buildings.* — Mr. Nasmyth has presented his magnificent picture map of the moon for the service of the Observatory. This very beautiful work of art (6 feet in diameter) was completed by Mr. Nasmyth from actual observation with a large telescope of his own construction in 1849.

IV. *Astronomical Work.*—During the past year this has been twofold. In the first place continuous attention has been devoted to the photography of small portions of the heavens with the view of determining the parallax of certain selected stars. In the first instance a careful trial of the method was made on the parallax of 61^1 and 61^2 Cygni, because the parallax of the point midway between the two stars had been determined, with presumedly great accuracy, by Bessel in 1838, whereby effective means of comparing the two methods were supplied. The general agreement of the result obtained from photography with that determined by this most able astronomer, together with the remarkable consistency of the individual photographic measurements, satisfied Prof. Pritchard not only of the great convenience, but also of the unimpeachable accuracy of the method. Dr. Pritchard has consequently much extended these operations for stellar parallax, and before the termination of the present year he hopes that the computation of the parallaxes of altogether some ten or twelve stars will be completed. The list will comprise 61^1 and 61^2 Cygni, μ Cassiopeiæ, and Polaris, which four stars may be regarded as already completed. Three more parallaxes have been *provisionally* determined from observations of *six months*,* viz. α, β, γ Cassiopeiæ; four others also are in a forward state. Experience has suggested that these stellar parallaxes will be most readily and efficiently determined by confining the photographic work on each star to those four periods of the year which, in respect of each parallactic ellipse, are the most effective for the purpose. It should be stated that for the purposes of accuracy four stars of comparison are selected, instead of the two with which astronomers have hitherto been generally contented. This photographic process enables Prof. Pritchard also, without much consumption of time, to measure from night to night the distance between the stars of comparison themselves, thus furnishing a check to the unavoidable variability of the scale of the focal field and of the photographic film. These operations are at present restricted to a systematic catalogue of stars of the second magnitude. It appears that astronomical work like this is well adapted to an Observatory connected with a great

University. It may be interesting to record the results of the computations so far obtained, viz.:—

61[1] Cygni	0″·4289	±0″·0180	α Cassiopeiæ	0″·072	±0″·042*
61[2] Cygni	0·4353	±0·0152	β Cassiopeiæ	0·187	±0·039*
μ Cassiopeiæ	0·0356	±0·0250	γ Cassiopeiæ	<0·05	±0·047*
Polaris	0·052	±0·0314			

The last result is peculiarly interesting, as it seems to furnish an instance where the resources of modern astronomy have arrived at the limits of their present possibility. The total number of plates taken for the purposes of the above investigation is approximately 700, and each plate has been measured with 120 bisections of the necessary stars, amounting altogether to about eighty-four thousand observations. Independently and concurrently with the preceding work Dr. Pritchard undertook for the Photographic Committee of the Royal Society the examination of two silver on glass mirrors of the same aperture but of very different focal lengths, with the view of ascertaining the practical effects of focal length on the photographic field. This work, owing to the temporary character of the mounting and the imperfection of the mechanical movement of the telescope, has been attended with great labour and personal endurance on the part of the observer, but at length it was brought to a successful conclusion, and the results have been communicated to and printed by the Royal Society. The expenses of the instrumental appliances connected with this investigation have been defrayed partly from a grant from the Royal Society, and partly by the generosity of Dr. De La Rue, to whom this Observatory owes so much, not only in the matter of pecuniary aid, but by his kindly encouragement and appreciation of our labours. The general result of the investigation alluded to above is the comparative unsuitability of any mirror for an extensive charting of the heavens, and particularly as regards mirrors of short focal length; but at the same time it leaves no doubt as to their capacity for the singularly accurate delineation of small portions of the heavens, and for such operations as those connected with stellar parallax, or the charting of the moon. Preparations were made for the necessary observations of the lunar eclipse of January 28 of this year; but, as was the unfortunate case with this and many other Observatories, they were rendered ineffectual by a clouded sky.

The above astronomical operations made under Dr. Pritchard's direction were skilfully and sedulously carried out by the two Observatory assistants, Mr. Plummer and Mr. Jenkins.

NOTES.

We learn that Dr. Guppy left England for Batavia on the 30th ult. with the intention of spending some time in the examination of the living and upraised coral reefs of the Indian Archipelago. Mr. John Murray has provided the necessary funds for the first six months of his sojourn in that region, and has directed Dr. Guppy in the first place to make as complete an examination as he can of the geological structure of Christmas Island. Judging from the important notes and collections made by Captain Aldrich and Mr. Lister during the recent visit of H.M.S. *Egeria*, this island would seem to be one of the oldest of the upraised coral islands, and as such it is likely to prove of considerable geological interest. At the last meeting of the Geographical Society, Captain Wharton, the Hydrographer, read a short paper on this subject.

Apparently we have missed our chance of solving the many interesting problems relating to the Antarctic regions. The matter has now been taken in hand by Germany, and we may be sure that she will not fail to carry out the enterprise in an energetic and thoroughly scientific spirit. The expedition is being organized by Dr. Neumayer, of the Hamburg Observatory.

Mr. Jesse Collings is to be congratulated on the result of his efforts to secure for the parish of West Lavington, Wiltshire, the full benefit of the Dauntsey Charity, a part of which the Charity Commissioners proposed to use for the establishment of a High School in some other place in Wiltshire. It is now proposed—with the approval of the Mercers' Company, the principal trustees and patrons of the Charity, who have agreed to undertake a liability of £60,000—not only that the children of the poorer inhabitants of West Lavington shall be provided with an ordinary elementary education, but that a fully-equipped Lower School for technical training in horticulture and agriculture shall be created for their benefit. It is intended that the latter school shall be adapted to the needs of persons who cannot afford to attend such institutions as those at Cirencester and Downton. If the scheme is carried out, land will be provided for the more thorough instruction of pupils, and classes will be formed for the teaching of the various sciences and arts which especially relate to agriculture.

On July 16, Prof. W. E. Ayrton will begin, at the City and Guilds of London Institute, a course of six lectures (to be delivered on Mondays, Wednesdays, and Fridays) on the construction, testing, and use of electrical measuring instruments. This course will include experimental lectures and special laboratory work. The lectures will comprise the principles and practice of the construction, calibration, and testing for faults of ammeters, voltmeters, ohmmeters, wattmeters, coulombmeters, and ergmeters as used for direct and alternating current systems. The students' practical work will be conducted in a laboratory specially fitted with accumulators, standard instruments, &c., for electrical instrument testing; and they will have the opportunity of examining and practically trying all the more important electrical meters at present in ordinary use.

An interesting Exhibition of hygiene and life-saving apparatus has been opened in the Park Léopold at Ostend. The exhibits are divided into the following sections:—Applications of geological, meteorological, and medical science to hygiene, industrial hygiene, maritime hygiene, domestic hygiene, hygiene of infancy, publications relating to hygiene, and life-saving apparatus.

At Messrs. Stevens' Sale Rooms on Monday, the 25th ult., a specimen of *Papilio caunus* from Assam was sold for £10. Mr. William Watkin, of Croydon, was the purchaser.

At the meeting of the Scientific Committee of the Royal Horticultural Society on June 26, Prof. Church contributed a summary of his highly interesting and important researches upon the presence of aluminium in the ashes of plants. This substance, instead of being peculiar to the species of Lycopodium, as once supposed, is found in minute traces in the ashes of very many others, a circumstance not to be wondered at, considering the abundant distribution of the element in many soils. It occurs in all the species of Lycopodium examined, except those which are of epiphytic habit, and which, consequently, do not directly derive their food from the soil. It does not occur in the allied genus Selaginella. It occurs in the ashes of some tree ferns in large proportions, sometimes forming as much as 20 per cent. of the ash, as in *Alsophila australis*, *Cyathea medullaris*; while from others it is all but absent. In the British species of ferns little or no alumina has been found.

At the same meeting Mr. McLachlan called attention to the notion that cold winters are injurious to insects—a notion he stated to be erroneous, although, no doubt, severe alternations of cold, heat, drought, or moisture, were prejudicial to insect life. During the present season it was noticed generally that great destruction of foliage occurred from caterpillars which destroyed the succulent portions of the leaf and tied the framework and fragments together by a web of fine threads comparable with spiders' webs. These caterpillars were different in different cases. In the oak they were species of Tortrix; in the apple the winter moth was destructive; while in other cases the larva of the Ermine moth was exceedingly hurtful to leaves.

THE *American Meteorological Journal*, desiring to attract the attention of students to tornadoes, in hopes that valuable results may be obtained, offers the following prizes:—For the best original essay on tornadoes or description of a tornado, 200 dollars will be given; for the second best, 50 dollars. Among those worthy of special mention 50 dollars will be divided. The essays must be sent to either of the editors, Prof. Harrington, Astronomical Observatory, Ann Arbor, Michigan, or A. Lawrence Rotch, Blue Hill Meteorological Observatory, Readville, Mass., U.S.A., before the first day of July, 1889. They must be signed by a *nom de plume*, and be accompanied by a sealed envelope addressed with the same *nom de plume* and inclosing the real name and address of the author. Three independent and capable judges will be selected to award the prizes; and the papers receiving them will be the property of the journal offering the prizes. A circular giving fuller details can be obtained by application to Prof. Harrington.

THE United States Congress has been discussing the question whether the Weather Bureau should be transferred to the proposed new Department of Agriculture. *Science* advocates the maintenance of the existing system. "The observations," it says, "upon which the Weather Bureau bases its calculations are now all made by enlisted men of the army, who have been specially instructed and trained for the work. No political influence whatever has been allowed to operate for their appointment, promotion, or retention in the service. It has been the aim of the Chief of the Signal Office to send to all important stations men who will be acceptable to the communities in which they are to live and do their work, but no member of Congress has been able to secure the transfer or removal of an observer sergeant in order that some favourite might be put in his place. The security which the observer sergeants have felt for the terms of their enlistment has certainly had a beneficial effect upon the character of the service they have rendered. It may seem an anomaly to the people that a duty that is in no respect of a military character should be done by soldiers rather than by civilians, but the military organization of the Weather Bureau has certainly resulted in keeping political influence from dictating in regard to the *personnel* of a class of men whose appointment and promotion it was very desirable to keep free from this influence."

THE Report of the Director of the Hong Kong Observatory for 1887 shows that the meteorological inquiries are being pushed on with vigour, and that the amount of information collected respecting the typhoons of the past year has been much greater than in previous years. Some of these results have been published in an appendix on the "Results of Further Researches concerning Typhoons"; and another work on the subject, with maps exhibiting the paths of the typhoons, is in preparation. This investigation will throw light on the cause of the frequency of these storms in the China Sea in September, and will enable masters of vessels to escape damage from them, and to make quicker voyages.

WE have received from Dr. Hellmann a very comprehensive and careful discussion of the rainfall of the Iberian Peninsula, being an excerpt paper from the Berlin *Zeitschrift der Gesellschaft für Erdkunde*, vol. xxiii. The principal results of the investigation were communicated to the Berlin Meteorological Society in January last (see NATURE, vol. xxxvii. p. 312). Dr. Hellmann, to whom we are indebted for many laborious inquiries, took advantage of his stay in Andalusia, in 1875–76, to collect all available materials, but found them insufficient for trustworthy results; the present discussion has therefore been delayed until the observations of ten more years could be added. The work deals with the monthly and yearly values for sixty-seven stations, for which a sufficiently long series could be got, and contains a map showing the yearly distribution of rainfall. The yearly and daily periods of rainfall, the monthly and yearly extremes, and the frequency, are also all fully and ably discussed. The annual fall is very various, being no less than 138 inches on the Serra da Estrella, and as little as 11 inches at Lérida, in Catalonia. In the yearly period the minimum fall at all stations occurs in July and August, and the maximum, generally speaking, about May or October, according to locality. Snow falls only in a few of the more elevated districts.

THE vapour-density of sulphur has been re-determined by Dr. Biltz in the laboratory of Prof. Victor Meyer, with unexpected results. It has hitherto been generally accepted that at a temperature (524° C.) not very far removed from its boiling-point (447° C.) the molecule of sulphur is built up of six atoms. This assumption is based upon vapour-density determinations by Dumas and Mitscherlich, who obtained values about this temperature pointing to a hexatomic molecule. However, the work of the last few years upon the chlorides of aluminium, tin, and iron, has opened the eyes of chemists to the fact that the double formulæ Al_2Cl_6, Sn_2Cl_4, and Fe_2Cl_6, resting as they did upon a few experiments performed within a very limited range of temperature, are erroneous, and have no foundation in fact. The older work upon the constitution of sulphur molecules was notably of this class. The experiments themselves were irreproachable, and completed with all the skill for which the experimenters were famous; but unfortunately the temperatures at which they worked were not sufficiently removed from each other, there being only a difference of 27° C. between their maxima and minima. It is now, moreover, a demonstrated law that the existence of molecules of fixed composition can only be assumed when the vapour-density remains constant within a notable interval of temperature. Hence a series of fresh determinations have been undertaken in the case of sulphur. Experiments conducted at 518° in a bath of vaporized pentasulphide of phosphorus by Dumas's method gave values averaging about 7·0, which are nearly coincident with Dumas's own. At the higher temperature of 606°, using a bath of stannous chloride vapour, the density had diminished to 4·7. At 860°, as is well known, sulphur vapour attains the normal constitution of two atoms to the molecule, and the density remains constant for about 200° higher still. Hence, in order to finally set the question at rest, a series of ten determinations were made at intervals of about 10°–15° from 468° to 606°, with the conclusive result that the density regularly diminished from 7·9 at the former to 4·7 at the latter temperature. Hence the notion of S_6 is completely dissipated; there is no more experimental reason for it than there is for the existence of molecules of the constitution S_5 or S_n. None but the value corresponding to the normal composition, S_2, stands the test of interval of temperature, therefore we must conclude that sulphur obeys the usual law, and that its molecules when completely vaporized are each composed of two atoms.

Science says that the logs from the great raft abandoned off the coast of New England a few months ago have drifted in a direction about east by south, and that the greater part of them are now in the region between the 33rd and 38th parallels and the 30th and 50th meridians. The reports lately received at the Hydrographic Office would seem to show that the general drift of the logs has been about east by south, and that most of them are now west-south-west from the Azores. Very few, if any, have drifted north of the 40th parallel. A great deal of timber has been reported further north, to the westward of the 20th meridian, but, from the descriptions given, it does not seem to be a part of the great raft.

In the twenty-first Annual Report of the Provost to the Trustees of the Peabody Institute, Baltimore, it is stated that whereas the number of readers during the past year declined, the number of books used increased. Thus the library "is being gradually converted into that real reference library for scholars which its founder intended to establish." A table included in the Report gives some interesting and suggestive information as to the subjects studied. Antiquities, philology, and theology seem to be the most popular subjects. On the first of these subjects 2894 volumes were read; on the second, 2336; on the third, 2212. Biography comes next; but there were readers for only 1,964 volumes under this heading.

The Register, for 1887-88, of the Johns Hopkins University of Baltimore has been sent to us. In an introductory statement it is explained that this University was opened in 1876; that thus far the Faculty of Philosophy has alone been fully organized; and that the formation of a Medical Faculty has been begun, and will soon receive further development. In the Faculty of Philosophy, instruction is carried on by University methods and by Collegiate methods corresponding with the requirements of students at different stages of their advancement. University instruction is offered to those who have already taken an academic degree, or who have otherwise fitted themselves to pursue advanced courses of study.

From the Report, just issued, of the trustees of the South African Museum for the year ended December 31, 1887, we learn that the condition of the collection generally has been satisfactorily maintained by dint of regular and frequent inspection. The donations during the year numbered 3125 specimens, presented by 78 donors, as compared with 1298 specimens, presented by 58 donors, in 1886. The trustees make an urgent appeal for the extension of the Museum buildings. "Each year," they point out, "has of necessity increased the overcrowding of the very limited available space, and this has now become a most serious hindrance to the usefulness of the Museum, and indeed an absolute barrier to its due development. The trustees have been disappointed to find that their repeated written representations on this important matter failed to meet with the favourable consideration of the Government, as they have thus been placed in the highly unsatisfactory position of inability to promote the normal growth of the institution, or even to insure the proper preservation of much of the valuable public property for which they are trustees."

The annual reports of the Aëronautical Society of Great Britain for the years 1885-86 have been issued in one small volume. Among the contents are the following papers, read at the annual meeting of the Society on December 11, 1886:—Gravity and wind-pressure on auxiliary powers in flight, by Sidney Hollands; balloon-signalling in war, by Eric Bruce; experimental ballooning, by F. W. Breary; an aërial boat, by Mr. Green; and jet-propulsion for aëronautical purposes, by Captain Griffiths.

We have received No. 5 of the first volume, fourth series, of the Memoirs and Proceedings of the Manchester Literary and Philosophical Society. It contains the following memoirs:—Descriptions of twenty-three new species of Hymenoptera, by P. Cameron; a survey of the genus Cypræa (Linn.), its nomenclature, geographical distribution, and distinctive affinities, with descriptions of two new species and several varieties (with two plates), by James Cosmo Melvill; a catalogue of the species and varieties of Cypræa, arranged on a new circular system, in accordance with true sequence of affinity, by James Cosmo Melvill; memoir of the late Prof. Balfour Stewart, F.R.S., by Prof. A. Schuster, F.R.S. To the last of these memoirs a list of the titles of papers by Prof. Balfour Stewart is appended.

A sixth edition of Mr. William Ford Stanley's "Mathematical Drawing and Measuring Instruments" (E. and F. N. Spon) has just been issued. It contains descriptions of twenty-five new instruments mounted or brought out since the publication of the fifth edition ten years ago. Among the instruments invented by the author himself is the oograph, designed for the purpose of enabling oologists to draw eggs of birds in their natural sizes and proportions.

A useful little volume on "Landscape Photography," by Mr. H. P. Robinson, has been issued as one of the series of "Photographic Handy-Books" (Piper and Carter). It consists of letters written to a friend "whose study of photography enabled him to produce a technically perfect negative, but who did not know how to put his knowledge to pictorial use." "They were not intended," the author explains, "to point out a royal road to art, but rather to act as a stimulus to activity in the search for subjects for the camera, and to teach how readiness of resource may help good fortune in turning them into agreeable pictures."

An interesting pamphlet on Pallas's sand grouse, by Mr. W. B. Tegetmeier, has just been issued (Horace Cox). It is illustrated with a coloured plate and woodcuts. "It is greatly to be regretted," says the author, "that a bird so beautiful in its form, harmless in its habits, valuable as an article of food, interesting to the sportsman as a game bird, and to the naturalist as the type of a most singular genus, should not be protected. The present pamphlet has been compiled as an endeavour to make the bird better known, to interest the public at large in the species, and thus, if possible, to aid in its preservation and naturalization as a British game bird."

Science states that Mr. William Walter Phelps has introduced into Congress a Bill to purchase from Stephen Vail, of Morristown, N J., the original telegraphic instrument, or recording receiver, invented by his father, Alfred Vail, and used upon the first telegraphic line ever constructed,—that between Washington and Baltimore,—and to transmit the first message ever sent: "What hath God wrought?" The purchase of this instrument is strongly recommended by the officers of the Smithsonian Institution. The price is ten thousand dollars.

According to an official notification of the Trustees of the Schwestern Fröhlich Stiftung at Vienna, certain donations and pensions will be granted from the funds of this charity this year, in accordance with the will of the testator, Miss Anna Fröhlich, to deserving persons of talent who have distinguished themselves in any of the branches of science, art, or literature, and who may be in want of pecuniary support, either through accident, illness, or infirmity consequent upon old age. The grant of such temporary or permanent assistance in the form of donations or pensions is, according to the terms of the foundation deed, primarily intended for natives of the Austrian Empire, but foreigners of every nationality—English and others—may likewise participate, provided they are resident in Austria. Information as to the terms and conditions of the foundation deeds, &c., may be obtained from the Austro-Hungarian Embassy in London.

The additions to the Zoological Society's Gardens during the past week include two Tasmanian Wolves (*Thylacinus cynocephalus*), two Bennett's Wallabys (*Halmaturus bennetti*), a Black and Yellow Cyclodus (*Cyclodus nigro-luteus*) from Tasmania, nine Silky Bower Birds (*Philonorhynchus violaceus*) from New South Wales, ten Laughing Kingfishers (*Dacelo gigantea*), ten Blue-cheeked Parrakeets (*Platycercus cyanogenys*), two Cereopsis Geese (*Cereopsis novæ-hollandiæ*), seven Maned Geese *Bernicla jubata*), two Black-backed Piping Crows (*Gymnorhina tibicen*), two Lace Monitors (*Varanus varius*), two Gould's Monitors (*Varanus gouldi*), a Gaimard's Rat Kangaroo (*Hypsiprymnus gaimardi*) from Australia, deposited; a Smooth

Snake (*Coronella lævis*), European, presented by Mr. Walter C. Blaker; a Dark-Green Snake (*Zamenis atrovirens*) from Dalmatia, an Æsculapian Snake (*Coluber æsculapii*), European, purchased; two Triangular-spotted Pigeons (*Columba guinea*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

AMERICAN OBSERVATORIES.—The Trustees of the Lick bequest formally made over the Lick Observatory to the University of California on June 1. The staff of the Observatory consists of Prof. Holden, Director; Messrs. Barnard, Burnham, Keeler, and Schaeberle, astronomers; and Mr. Chas. B. Hill, librarian and assistant-astronomer.

The Lick Observatory is not to be the most elevated of American Observatories. Mr. H. B. Chamberlin, of Denver, Colorado, is providing the University of that city with a new equatorial refractor of 20 inches aperture. The site chosen for the erection of this telescope is 5000 feet above sea-level, some 800 feet higher than the Lick Observatory.

Mr. W. R. Brooks, so well known for his cometary discoveries, has removed to the Observatory provided for him by the generosity of Mr. William Smith, of Geneva, New York. His present address is therefore "Smith Observatory, Geneva, N.Y."

The instruments of the Dearborn Observatory, Chicago, have been dismounted, and the old site abandoned, and a new building is to be erected at Evanston, about 16 miles north and 3 miles west of the old site, and some 250 feet from the shore of Lake Michigan, on grounds belonging to the North-Western University, with which institution the Observatory is in future to be connected, but without affecting its relationship to the Chicago Astronomical Society. The new building, which is to cost about £5000, and which will include a dome and tower for the 18½-inch refractor, a transit-room, library, and about eight other rooms, is the gift of Mr. James Hobbs.

Rochester, New York, has no fewer than seven Observatories, of which the Warner Observatory is the most important.

MINOR PLANETS.—The object discovered by M. Borelly on May 12 has proved to be Sironia, No. 116; the difference between the observed and predicted places being due to the omission of perturbations in the computation of the ephemeris. Herr Palisa's discovery of May 16 thus remains No. 278 as given in NATURE, vol. xxxviii. p. 89, at first. No. 272 has been named Antonia; No. 274 Philagoria.

THE RINGS OF SATURN.—Dom M. Lamey, Director of the Observatory of the Priory of St. John, Grignon, claims to have discovered four new rings around Saturn, outside those previously known. The first of these rings is said to commence at the extreme edge of that now known as the outer ring; the next reaches to the orbit of Enceladus; the third, which is the brightest, touches the orbit of Tethys; whilst the fourth and faintest lies between Dione and Rhea.

The distances from Saturn of the known rings have been measured by M. Perrotin, at Nice, with the following results:—

	Outer limit.	Cassinian division.	Dark ring. Outer limit.	Dark ring. Inner limit.
E. Ansa ...	11″·22 ...	8″·50 ...	4″·08 ...	1″·46
W. Ansa ...	11·12 ...	8·43 ...	4·07 ...	1·41

with an average probable error for each determination of ± 0″·02. These results agree well with those of Profs. O. Struve and Meyer, except in the case of those in the last column. The distances in the E. ansa appeared almost always greater than those in the W. ansa for the two outer points measured, but the measures of the dark ring are sometimes greater on one side, sometimes on the other. This is probably due to the revolution of the perisaturnium of the dark ring, which would appear to revolve round the planet in an elliptic orbit. The dark line known as Encke's division has not been seen in 1888, though seen in previous years; but on the other hand the inner part of the ring B has shown three faint divisions separating it into three nearly equal parts. The dark ring has appeared of a uniform tint, and no division has been detected in it.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 JULY 8–14.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 8

Sun rises, 3h. 56m.; souths, 12h. 4m. 51·1s.; sets, 20h. 14m.: right asc. on meridian, 7h. 12·3m.; decl. 22° 25′ N. Sidereal Time at Sunset, 15h. 23m.

Moon (New on July 9, 6h.) rises, 3h. 16m.; souths, 11h. 25m.; sets, 19h. 36m.: right asc. on meridian, 6h. 32·5m.; decl. 21° 11′ N.

ELECTRICAL NOTES.

PROF. NICHOLS, of the Cornell University, has suggested the use of carbon and copper combined to form a compensated resistance standard. The resistance of metals increases with temperature, but that of carbon diminishes. The movement of copper is + 0·384, that of carbon − 0·0235 per cent. per degree Centigrade. For every ohm of carbon, 11·544 ohms of copper are needed to secure complete compensation for temperature.

Prof. Nichols electroplates a strip 1 millimetre wide of the carbon rod parallel to the axis with copper to the required thickness. The influence of temperature up to 100° C. is then entirely imperceptible.

MESSRS. GLAZEBROOK AND FITZPATRICK have once more utilized the resources of the Cavendish Laboratory to determine the specific resistance of mercury, and therefore the value of the ohm (10^9 C.G.S. units of resistance). The result, together with the most recent determinations, is given in the following table:—

Observer.	Date.	Value of Siemens unit in B.A. units.	Value of ohm in centimetres of mercury at 0°.
Lord Rayleigh and Mrs. Sidgwick ...	1883	0·95412	106·23
Mascart, Nerville, and Benoit... ...	1884	0·95374	106·33
Strecker	1885	0·95334	106·32
L. Lorentz	1885	0·95388	105·93
Rowland	1887	0·95349	106·32
Kohlrausch	1888	0·95331	106·32
Glazebrook and Fitzpatrick	1888	0·95352	106·29
Wuilleumier	1888	0·95355	106·27

The specific resistance of mercury at 0° C. is therefore 95352 C.G.S. units.

THE mean of the values in centimetres of mercury—106·3—omitting Lorentz's, must be considered a very close approximation to the true ohm. We thus have

B.A. unit	104·808 cm.
Legal ohm	106
Ohm	106·3

The B.A. unit is thus 1·347 per cent. wrong.

WHAT is the specific resistance of pure copper? is a curious question to ask in 1888, but Mr. G. P. Prescott asks it in the *Electrical Engineer* of New York. He points out that Ayrton gives it as 1·599, and Stewart and Gee 1·616, legal microhms, at the same temperature, 0° C. He also shows that Matthiessen and Jenkin did not agree; they differed 2·3 per cent. Messrs. Glazebrook and Fitzpatrick, who have done such good work with mercury, might well turn their attention to copper. It is well known that Matthiessen's standard for pure copper is wrong. It was one English standard mile of pure annealed copper wire 1/16 inch in diameter at 15°·5 C., having a resistance equal to 13·59 B.A. units. It is a common thing to get copper giving better results than this.

THE magnetic elements for 1887 as determined at Greenwich were—

Mean declination	17° 47′ W.
Mean horizontal force	181·75
Mean dip	67° 26′ 20″

Why does the Astronomer-Royal retain British and metric units when nearly all the world uses C.G.S. units?

THE MICRO-ORGANISMS OF AIR AND WATER.

EVER since the great importance of micro-organisms in the economy of Nature was pointed out by Pasteur now some twenty-five years ago, the presence of these minute living forms in the two great fluid media—air and water—with which we are surrounded, has formed the subject of elaborate investigations. As these investigations are thus co-extensive with the period during which micro-organisms have been made the subject of careful study, a review of them becomes particularly instructive as illustrating the gradual development of the methods of bacteriology from the earliest times up to the high degree of perfection to which they have attained at the present day.

It was Pasteur himself who first instituted a systematic inquiry into the presence and distribution of micro-organisms in the atmosphere in connection with his well-known researches disproving the spontaneous generation of life. The experiments which he undertook for this purpose are as remarkable for their extreme simplicity as for the striking results which they yielded. Thus the apparatus with which Pasteur set about exploring the distribution of microbes in the air consisted simply of a number of small flasks, each partially filled with a putrescible liquid such as broth; the necks of these flasks were drawn out and sealed before the blow-pipe whilst the fluid contents were in active ebullition. The flasks thus prepared were both vacuous and sterile, and could be preserved for an indefinite length of time without the contained liquid undergoing change. A number of these flasks were then momentarily opened in various places—in Paris, in the open country, at various altitudes in the Jura Mountains, and at an elevation of 6000 feet at the Montanvert, near Chamonix. Each flask on being opened became instantly filled with the air of the place in question, whilst, by sealing the flask directly afterwards, the further access of air was prevented. On preserving these flasks which had been thus opened, the liquid of some was found to become turbid and lose its transparency owing to the development of bacterial life within it, whilst in others it remained perfectly clear and translucent. It was further observed that the proportion of flasks becoming so affected varied greatly according to the places where they had been exposed. Thus, of twenty flasks exposed in the open country near Arbois, eight developed living organisms; of twenty opened on the lower heights of the Jura Mountains, five became affected; whilst of the twenty opened at the Montanvert, close to the Mer de Glace, only one broke down. The proportion of flasks which became affected on being similarly exposed in Paris, was considerably greater than in the case of the experiment made at Arbois.

The results of these simple experiments thus convey a most vivid picture of the great density of microbial life in the air of towns, and of its attenuation in the higher regions of the atmosphere, although they can give no account of the *actual* numbers present in the air under examination.

Miquel and Freudenreich [1] made the first step in the quantitative estimation of aërial microbes by aspirating air through plugs of glass-wool, thus taking advantage of a fact long known—that it is impossible for micro-organisms to pass through sufficiently tightly constructed plugs of such materials.

Without entering into a detailed account of this method, the merits and demerits of which have been fully discussed by German investigators, it is sufficient to state that a very large number of experiments have been carried out by the authors which can lay claim to a fair degree of accuracy. However, since solid nourishing media for the cultivation of micro-organisms were introduced by Koch, the importance of substituting the latter for the liquid media hitherto exclusively employed has led experimenters to devise processes which shall render their use possible in the examination of air.

The advantages possessed by solid over fluid media are very great, for whereas in fluid media, such as broth, the organisms are in no way restricted in their movements, and their multiplication can take place indiscriminately throughout the entire liquid, on the other hand, if they are introduced into gelatine-peptone which has been first melted, they can be evenly dispersed throughout the culture-material by gentle agitation, and by subsequently allowing it to solidify they are not only isolated, but rigidly confined to one spot. Thus each individual organism becomes a centre round which extensive multiplication takes place, and in a few days definite points of growth are visible to the naked eye, which are appropriately described as "colonies," and which can be easily counted with the aid of a low magnifying glass. Although each colony consists of many thousands or even millions of individual microbes, yet as in the first instance they owe their origin to a single organism or indivisible group of organisms, it is correct to regard the number of colonies as representing the number of micro-organisms. These colonies have often very beautiful and characteristic appearances, [2] and it is exceedingly remarkable how constant and distinct for one and the same organism these appearances are. In many cases they give rise to magnificent patches of colour—deep orange, chrome yellow, brown, various shades of red, green, black, &c. Often under a low magnifying power they are seen to spread over the surface of the gelatine, producing tangled networks of threads, sometimes they resemble the petals of a flower, sometimes the roots of a tree or its branches; in fact, one is constantly startled by the novelty and beauty of their modes of growth.

Koch [3] and, later, Hesse [4] have devised methods by which the organisms in the air become deposited on a solid surface of gelatine-peptone, and by there producing colonies render their estimation possible. A large number of experiments have been

[3] *Mittheilungen aus dem kaiserlichen Gesundheitsamte*, 1881, Bd. i.
[4] *Ibid.*, 1883, Bd. ii.

made with Hesse's method, which consists in aspirating air through glass tubes about 3 feet in length, coated internally with a film of gelatine-peptone. The organisms, owing to the property they possess of rapidly subsiding in the absence of disturbing influences, fall on the surface of the gelatine, and give rise to colonies.

The following series of observations was made by this method in 1886[1] on the roof of the Science Schools, South Kensington Museum, in order to trace the seasonal variations in the number of micro-organisms present in the air of one and the same place. The following are the averages obtained for each month during which these observations were made:—

Number of Micro-organisms found in Ten Litres (Two Gallons) of Air.

January	4	August	105
March	26	September	43
May	31	October	35
June	54	November	13
July	63	December	20

From these figures it will be seen that it is during the summer that the largest number of micro-organisms are found in the air, whilst the smallest average number was recorded in the month of January.

The air at sea, the air at higher altitudes, and the air in sewers, have all been explored by means of Hesse's method.

Thus Dr. Fischer,[2] in experiments carried on at sea, found that beyond a distance of 120 sea miles from land micro-organisms were invariably absent. And, inasmuch as micro-organisms are abundantly present in sea-water, it thus appears that no micro-organisms are communicated to the air from the water even when the latter is much disturbed. Moreover, as might have been anticipated, this complete freedom from micro-organisms was attained even in close proximity to land, provided the wind had passed over the above-mentioned distance of sea.

As regards the air at higher altitudes, experiments have been made on the dome of St. Paul's, in London, and on the spire of Norwich Cathedral, which show that even in ascending to such modest elevations in densely-populated centres, the number of micro-organisms suspended in the air undergoes very marked diminution.

Thus, on the top of Norwich Cathedral spire, at a height of about 300 feet, I found in ten litres (two gallons) of air only seven micro-organisms, and on the tower, about 180 feet high, I found nine, whilst at the base of the Cathedral, in the Close, eighteen were found. These results are fully confirmed by another series of experiments made at St. Paul's Cathedral. In this case the air examined from the Golden Gallery yielded in the same volume eleven, that from the Stone Gallery thirty-four, whilst in the churchyard there were seventy micro-organisms present.

The contrast between town and country air, and even between the air of the London parks and streets is also exceedingly sharp. In Hyde Park—the place selected for the experiment being as far removed from roads and traffic as possible—I found eighteen, whilst on the same day, June 7, the air in the Exhibition Road, South Kensington, yielded as many as ninety-four. On the following day, however, when the traffic was very great, and the air was consequently heavily laden with dust, the number rose to 554. This is in marked contrast to the microbial condition of country air, for on the Surrey Downs in the same volume only two micro-organisms were found; and in the case of an extensive heath near Norwich only seven.

Within doors we find that the number of micro-organisms suspended in the air depends, as we should have expected, upon the number of people present, and the amount of disturbance of the air which is taking place. Thus, on examining the air in the large entrance hall of the Natural History Museum in Cromwell Road it was found to yield under ordinary conditions from fifty to seventy organisms in the same volume (two gallons), but on Whit Monday, when an immense number of visitors were present in the building, I found as many as 280. Again, on a paying day at the South Kensington Museum, about eighteen micro-organisms were found, but on the Saturday, when no entrance fee is charged, there were as many as seventy-three in the same volume of air.

[2] "Bacteriologische Untersuchungen auf einer Reise nach Westindien," *Zeitschrift für Hygiene*, Bd. i. Heft 3.

The air of sewers has been shown by Carnelley in this country, and by Petri in Berlin, to be remarkably free from micro-organisms, the number being almost invariably less than in outside air. That this should be the case is only natural when the moist nature of the walls and the absence of dust in these subterranean channels is borne in mind, and although their liquid contents is teeming with bacterial life, there is no reason why the latter should be carried into the air provided no effervescence or splashing takes place. On the other hand, if the contents of a sewer enter into fermentation and bubbles of gas become disengaged, minute particles of liquid with the living matter present may be carried to great distances, and it must not, therefore, be too hastily concluded that because sewer air is generally remarkably free from micro-organisms, that, therefore, a visit to the sewers should be attended with such beneficial results as a trip to sea or the ascent of a mountain summit!

During the use of Hesse's method I became acquainted with several serious defects which it possessed, and in order to overcome these disadvantages I was led to devise a new process[1] for the examination of air. This consists essentially in aspirating a given volume of air through a small glass tube, not more than 4 inches long and ¼ inch in width, which is provided with two filter-plugs, the first of which is more pervious than the second, and consists of glass-wool coated with sugar, whilst the second contains, in addition, a layer, ⅛ inch in thickness, of fine sugar-powder. On these plugs the microbes suspended in the aspirated air are deposited, and each of these plugs is then introduced into a separate flask containing a small quantity of melted gelatine-peptone; with this the plug is agitated until it becomes completely disintegrated, and since the sugar-coating of the glass-wool dissolves in the liquid gelatine, the microbes become immediately detached. The contents of the flask are then made to congeal in the form of a thin film over its inner surface. The flasks are then preserved at a suitable temperature, and in the course of a few days the colonies derived from the organisms, which were collected by the plug, make their appearance and can be counted and further studied. Now, if the plug has been properly constructed, the flask into which the second or more impervious plug has been introduced will be found to remain quite sterile, clearly showing that the first plug has arrested all the microbes suspended in the aspirated air. This method yields results which agree not only very closely amongst themselves, but also with those obtained by Hesse's method, if the experiments are made in still air, which is the condition necessary for an accurate result being obtained with a Hesse tube. As this new method is equally applicable in disturbed air, it possesses great advantages over Hesse's, and is, moreover, considerably more convenient, as it renders possible the examination of a far larger volume of air in a very much shorter space of time, the apparatus required being also exceedingly portable.

Of the presence of pathogenic or disease-producing micro-organisms in air, there is little or no direct evidence so far; it must, however, be remembered that it is just in the case of those extremely infectious diseases, such as measles, whooping-cough, &c., in which the virus might be expected to be carried through the air, that the exciting organized poisons have not yet been discovered and identified.

The investigations on aërial microbia, so far as they have as yet been carried, are of service in indicating how we may escape from all micro-organisms, whether harmful or harmless; and secondly, how we may avoid the conveyance of micro-organisms into the atmosphere from places where pathogenic forms are known or likely to be present. This acquaintance with the distribution of micro-organisms in general, and the power of controlling their dissemination which it confers, is really of far wider practical importance than discovering whether some particular pathogenic form is present in some particular sample of air. It is this knowledge which has led to the vast improvements in the construction and arrangement of hospital wards and of sick-rooms generally, and which has directed attention to the importance of avoiding all circumstances tending to disturb and distribute dust. It is, moreover, this knowledge of the distribution of micro-organisms in our surroundings which has formed one of the foundations for the antiseptic treatment of wounds—that great step in surgery with which the name of Sir Joseph Lister is associated.

Micro-organisms in Water.

The micro-organisms present in water have long been studied by direct observation with the microscope. Such observations can, however, only be made in the case of foul waters in which bacterial life is very abundant, and even in such cases the information gained by the microscope alone has but little value. It is to the modern methods of cultivation, more especially those in which solid media are employed, that our increased knowledge concerning these primitive inhabitants of water is due. Thus the beautiful process of plate-cultivation introduced by Koch,[1] and to which more than to anything else the recent advances in bacteriology are due, has been of the greatest service in the investigation of a number of questions bearing on the micro-organisms in water. The method of plate-cultivation consists, as is well known, in taking some of the liquid or other substance under examination for micro-organisms and mixing it with melted gelatine-peptone in a test-tube, the mixture being then poured out on a horizontal plate of glass and allowed to congeal, the plate being then preserved in a damp chamber at a suitable temperature. In the course of a few days colonies make their appearance in the gelatine film, and can be counted and further studied as required. This process is of extremely wide application, for by this means pure cultivations of the various organisms in a mixture can be readily obtained. If a definite volume of water be submitted to this method of plate-cultivation, the resulting colonies on the plate clearly indicate both the number and the character of the organisms present in it.

From numerous investigations made by means of gelatine plate-cultivations, it appears that whilst surface waters, such as rivers, contain an abundance of microbial life, waters, which like those from springs and deep wells have undergone filtration through porous strata, contain but very few micro-organisms. Now since such underground waters have at some time or other been surface waters, it is obvious that in passing through the porous strata of the earth they have been deprived of those microbes which they contained whilst at the surface. This removal of micro-organisms from water[2] also takes place in a very marked manner when it is submitted to some kinds of artificial filtration, such as that through very finely divided coke or charcoal, as well as in the filtration of water on the large scale through sand. The process of filtration, however, which absolutely removes microbes with the greatest degree of certainty is that introduced by Pasteur, in which the water is forced through porous porcelain. It is especially noticeable that the efficiency exhibited by these various materials in removing micro-organisms stands in no sort of relationship to their chemical activity, *i.e.* power of removing organic matter from water. Thus the porous porcelain produces practically no change whatever in the chemical composition of the water, whilst it deprives it entirely of micro-organisms.

The relative abundance of bacterial life in surface water, in deep well water, as well as in surface water after filtration through sand on the large scale, is well illustrated by the following results.

Thus the average number of micro-organisms obtained during the past year from a cubic centimetre (about twenty drops) of the raw water as abstracted from the Rivers Thames and Lea by the metropolitan water companies was 21,500 and 13,200 respectively. The same water, however, after having undergone storage and filtration contained on an average respectively 500 and 450 micro-organisms in 1 cubic centimetre. It is at once apparent, therefore, what striking results can be obtained by sand filtration as at present carried out, and there is no doubt that with the introduction of fresh improvements and increased care an even greater reduction will be effected.

In deep well water obtained from the chalk, which has undergone no artificial filtration, we find the remarkably low number of eighteen as the average for the year. Thus the artificial filtration through sand is far surpassed by the exhaustive filtration through vast thicknesses of porous strata.

Another point which has been brought to light through investigating the micro-organisms of water by means of the improved methods which we now possess is that many of the microbes found in natural waters are capable of the most abundant multiplication[3] in the absence of practically any organic matter whatever. Thus, if the deep well water referred to above is preserved for several days thoroughly protected from contamination through the air, and is then examined for micro-organisms, it will be found that these have undergone an enormous increase, 1 cubic centimetre containing many thousands instead of the ten or twenty usually present in the water at the time of pumping. It has been found, moreover, that some of the water-organisms are even capable of such abundant multiplication in water which has been several times redistilled, and which is, therefore, almost absolutely pure. From what source such organisms obtain their necessary nourishment under these circumstances has not yet been determined. The following figures serve to illustrate the extent to which multiplication of this kind may take place:—

Number of Micro-organisms obtained from 1 cubic centimetre of water.

	Day of Collection.	Standing 1 day at 20° C.	Standing 3 days at 20° C.
Sample of water from Kent Co.'s deep well in chalk	7	21	495,000

It is often urged that the bacteriological examination of water is of little practical importance, inasmuch as the micro-organisms found are not necessarily prejudicial to health, and that the method of examination does not aim at the detection of harmful forms. A little more mature consideration, however, will show that the actual detection of harmful or pathogenic forms is a matter of very little importance, and that if methods of water purification are successful in removing micro-organisms in general, and more especially those which find a suitable home in natural waters, there can be no serious doubt that they will be equally successful in removing harmful forms, which are not specially adapted for life in water. Could it be, for instance, reasonably contested that a method of purification which is capable of removing the *Bacillus aquatilis* from water, would be incapable of disposing of the *Bacillus anthracis* when suspended in the same medium? The supposition is, on the face of it, absurd, and not a particle of experimental evidence can be adduced in its favour. It is, therefore only rational to conclude that those methods of water purification, both natural and artificial, which succeed in most reducing the total number of micro-organisms, will also succeed in most reducing the number of harmful forms should they be present.

As a matter of fact, however, pathogenic forms can and have been discovered in waters by the process of plate-cultivation; thus the "comma-bacillus," which is by many authorities regarded as the cause of Asiatic cholera, was found by Koch in some tank-water in India, and the bacillus which with more or less probability is identified with typhoid fever has by Chantemesse and Widal been discovered in the drinking-water which had been consumed by persons suffering from that disease.

On the other hand, the examination of water for the number of micro-organisms present can have no value if the multiplication referred to above has taken place. Thus, if the number of micro-organisms present in a water is to throw light on the natural purification it has undergone, the sample for examination must be taken as near as possible to the point where it issues from the water-bearing stratum, and, in the case of artificially purified water, as soon as possible after it has left the purifying apparatus.

Of much more importance than the discovery of pathogenic organisms in particular waters is the problem of ascertaining the fate of pathogenic forms, when these are introduced into waters of different kinds. A considerable amount of work has been done in this direction with a number of typical pathogenic forms,[1] and some very remarkable results have been obtained. Thus it has been found that the bacilli of anthrax do not survive many hours on being introduced into ordinary drinking-water; their spores, however, are not in any way affected by such immersion, and even in distilled water the latter retain their vitality for practically an indefinite length of time. In polluted water, such as sewage, on the other hand, not only do the bacilli not succumb, but they undergo extensive multiplication. Similarly Koch's "comma-bacillus" was found to flourish in sewage, being still present in very large numbers after eleven months' residence in this medium. In deep-well and filtered Thames water, on the other hand, although the "comma-bacilli" were

[1] "Die Vermehrung der Bacterien im Wasser" Wolffhügel und Riedel, *Arbeiten a. d. kaiserlichen Gesundheitsamte*. "Ueber das Verhalten, &c.," Meade Bolton. "On the Multiplication of Micro-organisms," Proc. Roy. Soc.; also "Recent Bacteriological Research in connection with Water Supply," Soc. Chem. Ind., vol. vi. No. 5.

still demonstrable after nine days, they were only present in small numbers. Much less vitality is exhibited by the micrococcus of erysipelas when introduced into waters of various kinds, for even in sewage this organism was not demonstrable on the fifth day. In fact, all the pathogenic micrococci which have been experimented with in this manner exhibit but little vitality under similar circumstances.

From these experiments it appears, therefore, that whilst ordinary drinking-water does not form a suitable medium for the extensive growth and multiplication of those pathogenic forms which have hitherto been made the subject of investigation in this respect, yet, that in the condition of spores, they are extremely permanent in any kind of water, however pure, and that even those of which no spores are known may often be preserved for days or even weeks.

Thus the investigations which have hitherto been made on the micro-organisms both of air and water, by the light which they throw on the behaviour of micro organisms in general in these media, the manner in which they may be preserved and the manner in which they may be removed, are of great service in indicating how the spread of zymotic diseases through these media is to be avoided.

Until we are fully acquainted with all pathogenic forms of microbes, a consummation which is certainly not likely to be attained in the near future, it is obvious that in endeavouring to exclude dangerous organisms we must attempt to exclude *all* organisms, *e.g.* in the purification of water which has been exposed to possibly noxious pollution, that process of purification which insures the removal or destruction of the greatest proportion of micro-organisms must be regarded as the most efficient. In just the same way as in the antiseptic treatment of wounds, the preventive measures employed by surgeons are of such a nature as to destroy or preclude the possibility of growth of *any* microbes whatever, and not only of those known to be capable of causing mischief.

PERCY F. FRANKLAND.

THE OPENING OF THE MARINE BIOLOGICAL LABORATORY AT PLYMOUTH.

THE Laboratory erected at Plymouth by the Marine Biological Association of the United Kingdom, of which a full account was given last week in NATURE, was opened on Saturday, June 30. The weather was fine, and at ten o'clock a large and distinguished company were present. Having viewed the tanks, the company assembled in the Laboratory, where Prof. W. H. Flower, C.B., F.R.S., Director of the Natural History Department of the British Museum, delivered an address, in the course of which he said :—"The necessity for such institutions as this has been felt almost simultaneously throughout the cultivated nations of the world. The British Isles, with their extensive and varied seaboard, offering marvellous facilities for the investigation of marine life, with their vast economical interests in the denizens of the waters that lave their shores, have been rather behind some other countries in adopting this line of research. Let us hope, however, that being so, we may profit by example and the experience of others, and ultimately, as in so many other similar cases, may outstrip our neighbours in a department of work for which our maritime and insular position seems so specially to fit us. That our country should be alone in neglecting this branch of scientific inquiry was impossible. Stations for the investigation of the phenomena of marine life have been founded at several places on the northern coasts of our island, but all on a very limited scale. An institution commensurate with the importance of the subject and of the nation had to be established sooner or later ; the only questions to be solved were when it was to be founded and where it was to be placed. Much of the success of an enterprise must depend upon the particular time selected for embarking upon it. If delayed too long, the world is a loser by the non-existence of the knowledge that is to be gained from it. On the other hand, premature attempts before sufficient interest in the subject is awakened, or before sufficient information as to the best means of carrying it out has been gained, often end in failure. I think that in this respect we have taken the right medium." After a reference to the Fisheries Exhibition, Prof. Flower continued:—"The question as to the place at which our head-quarters were to be established was at first one of considerable difficulty. Many were the rival claimants, but Plymouth was finally chosen as best approaching the requisite physical and geographical surroundings for such an institution ; and the cordiality with which the Association was welcomed by its leading citizens was in itself a ground of justification for the choice. Though a portion of the old military defences of the town has been given up to our peaceful enterprise, we trust the safety of the inhabitants will not suffer. The Laboratory now stands beneath the Plymouth Citadel and the sea, and an enemy entering the town by the most direct route would have to march over the ruins of the building. That consideration alone should be enough to secure your safety in a war with many of the enlightened science-loving nations of Europe, should such an event unhappily arise. As to the institution itself, few words are needed to show how excellent is its adaptation to the purpose for which it is founded. Although still not in all respects in full working order, we have been all enabled to see to-day how carefully it has been planned, and how well the design has been carried out. We have secured a capable and energetic working staff, students are already taking their places at our laboratory tables, and already a commencement has been made in their original investigations and contributions to knowledge, which we hope will be of such a character and of such abundance as to give this Laboratory a high place among the scientific institutions of the world. Our present financial position and our future needs are fully set forth in the report of the Council, just issued. This shows that of our capital already subscribed the greater part has been expended on the building and the necessary apparatus for its equipment. We still want a steam-vessel for the use of the staff in exploring the fishing grounds of the neighbourhood and for collecting materials to stock our tanks ; and for the means of providing this, and for the annual maintenance of our establishment in a state of efficiency, we shall require further pecuniary assistance. But as the report is, or shortly will be in your hands, I need not detain you longer by enlarging upon its contents. I will therefore, in the name of the President and Council of the Marine Biological Association of the United Kingdom, thank all those who have, by their generous contribution of money or by expenditure of their time, labour, and thought, brought us so far on our way, and declare the Laboratory of the Association open for work. May we all join in the earnest hope that the expectations which have been raised of its future usefulness may never be disappointed."

The company, after being photographed, adjourned to the Grand Hotel on the Hoe, where they sat down to a *déjeûner* given by the Fishmongers' Company. Sir James Lawrence, Prime Warden of the Fishmongers' Company, presided, and was supported by the Earl of Morley, Prof. Flower, Sir H. W. Acland, K.C.B., F.R.S, the Mayor of Plymouth (Mr. H. J. Waring), the Mayor of Devonport (Mr. J. W. W. Ryder), the Chairman of the Stonehouse Local Board (Mr. E. A. Lyons), Prof. E. Ray Lankester, LL.D., F.R.S., Sir Edwin Saunders, Sir George Paget, K.C.B., F.R.S., the Ven. Archdeacon Wilkinson, Prof. A. Milnes Marshall, F.R.S., Prof. Charles Stewart, Mr. J. Evans, P.S.A., F.R.S., Captain Wharton, R.N., F.R.S., the Vice-Chancellor of Cambridge, Sir Edward Watkin, M.P., Prof. J. W. Groves, Rear-Admiral H. D. Grant, C.B., Major-General T. C. Lyons, C.B., Mr. Thiselton Dyer, C.M.G., F.R.S., Mr. A. Sedgwick, F.R.S., Mr. W. Pengelly, F.R.S., Mr. F. Crisp, F.R.S., Colonel Hewet, R.E., Rev. J. Hall Parlby, Dr. A. Günther, F.R.S., Major-General Barton, R.E., Captain Inskep, R.M., Mr. Robert Bayly, Prof. F. Jeffery Bell, Prof. D'Arcy Thompson, Prof. G. B. Howes, Mr. C. Spence Bate, F.R.S., Prof. M. Foster, Mr. W. Lant Carpenter, Mr. E. W. N. Holdsworth, Mr. E. L. Beckwith, Fishmongers' Company, Mr. Gilbert C. Bourne, and Mr. J. Solly Foster and Mr. John Hall, Wardens, Fishmongers' Company.

The health of "The Queen" having been given by the Chairman, Lord Morley proposed "The Marine Biological Association of the United Kingdom." He said he was sure that his friends the Mayors of Plymouth and Devonport would join with him in wishing a hearty welcome to the Association, and in sincerely hoping that the Laboratory would prove a success. Any doubt as to the practical value of the Laboratory was dissipated by the fact that the Chairman was one of its main founders, and also that many well-known gentlemen, including the Chairman of the National Association at Kensington and Kew, anticipated good results therefrom. Since there was such a consensus of opinion as to the importance of the scheme from a practical and scientific point of view, the thing which surprised him was why it was not done before. We reaped the richest harvest from the sea, and yet we had never inquired scientifically into the source of this great industry. We had lagged behind other nations in this respect. France had no less than four institutions of a similar kind; Austria, with its small coast, had one at Trieste; and the German Government endowed their Laboratory at Naples, which was the most complete in existence, with £1500 a year. From certain statistics recently given to Parliament by the Board of Trade, they learned that the production of fish in the United Kingdom of Great Britain and Ireland last year amounted in value to six and a quarter millions, and if they took the retail value and not the wholesale value, as put in the statistics, it would amount to not less than thirteen millions per year. The east coast was by far the most fruitful of all our coasts as regards the fishing industry, Grimsby, Hull, Lowestoft, and Yarmouth producing £2,800,000 worth of fish. Plymouth with its £96,000 worth of fish per year, Brixham with its £56,000, and Penzance with its £41,000, gave some idea of what the sea produced in the shape of food. Comparing these figures with other countries, it would be found that Canada did not produce four millions worth of fish, and France even less. Then they ought to consider the immense amount of traffic our fishing industry gave to our railways. From Plymouth alone there were sent on two lines of railway 50,000 tons of fish annually. It seemed to him an extraordinary thing that so many years should have elapsed before scientific methods were adopted for learning the conditions under which fish live. If they read the interesting Reports of the Trawling and Fishing Commission, they would be surprised at the ignorance of fishermen as to the habits of fish, their modes of existence, their food, and the climatic and other effects which influenced their existence and modes of living, and he was afraid that ignorance was not confined to fishermen. The great want was, he hoped, about to be supplied in the establishment of this Laboratory. In heartily wishing success to the Marine Biological Association of the United Kingdom, he had the greatest possible pleasure in coupling with it the name of Prof. Ray Lankester.

Prof. Ray Lankester said it was with feelings of pride that he rose to return thanks. It was the great Fisheries Exhibition which suggested the movement for the formation of a laboratory where fishery studies could be carried on. The idea they had in view at that time, or rather the institution existing elsewhere which they wished to copy, was that established by Dr. Dohrn at Naples, with which they were all familiar. The question was, How could such a laboratory be put up on the British coast? And it was to his friend Dr. Günther, of the British Museum, that they owed the suggestion of the formation of an Association. It was to the officers of the Royal Society that they owed the opportunity of starting the Association. A meeting was called in the rooms of that Society, and presided over by the illustrious President of the great scientific institution, which was also the first public body to support the funds of the Association with a large and handsome subscription, and was very largely attended by men of science and gentlemen interested in fisheries, while the late Earl of Dalhousie, one of their most ardent supporters, the Duke of Argyll, and other public men took part in it. The newspaper Press had all along helped them in a most admirable and cheering manner. The *Times* had been their warmest friend, and he hoped it would continue to be so for years to come. No sooner had the first start been made at the meeting in the rooms of the Royal Society and the subscription list put forward than many other big societies came in and individuals throughout the country put down their money, as did also the Universities of Oxford and Cambridge. Subscriptions had been received from purely scientific bodies and individuals to the amount of £3000, and from various sources a total sum of £16,000 to £17,000 had been obtained. The most important item of support given to the Association was the grant from Her Majesty's Government of £5000 and £500 a year. The remaining £10,000 they owed to the great civic Companies and to munificent individuals, among whom he must not omit to mention with hearty gratitude their friends Mr. John Bayley and Mr. Robert Bayley, of Plymouth. No sooner had the enterprise been set on foot than His Royal Highness the Prince of Wales expressed his desire to become the patron of the institution, and support came in from every side. The Inspector-General of Fortifications and the Earl of Morley were instrumental—were, in fact, the actual causes of their receiving the grant of the splendid site on which the building had been erected; and the co-operation and consent of the Town Council of Plymouth, who had certain rights over the area, were cheerfully given. They had now arrived at a definite stage in their work: the building was completed, the laboratory was equipped, the naturalists were on the spot, and they had thus, as he had said, accomplished what he considered to be the first step in the work of the Association. But it was only the first step. Beyond the mere existence of the laboratory building, they had still to justify themselves in the eyes of their supporters by the work that was done within it. He thought they might rely upon the staff they had been fortunate enough to obtain. He had the greatest confidence in the work that would be done in the institution, and in the direction which would be given to that work by his friend Mr. Gilbert Bourne, assisted by the experience of his friend Mr. J. T. Cunningham, who had come to them fresh from his work in Scotland, and students of all ages. He would mention once more a subject which had been already alluded to. They wanted a yacht of their own—not a pleasure-yacht, but a steam sea-going vessel which could accompany the trawlers on their expeditions, and should be a thoroughly seaworthy boat. He hoped that those who were able to place additional funds at their disposal, and who had been pleased and gratified with the way in which they had expended the money already intrusted to them, would not delay to add to the resources of the Association so as to enable them to purchase this steamer.

The Prime Warden then proposed "Prosperity to Plymouth," and the Mayor of Plymouth replied.

Sir George Paget, K.C.B., proposed the health of the Prime Warden, who responded, and three cheers having been given for the Fishmongers' Company, the guests dispersed.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following have been placed in the first class in the Natural Sciences Tripos, Part I. (the names are in alphabetical order):—Baily, Joh.; Daniel, Trin.; Falkener, King's; Hankin, Joh.; Horton-Smith, Joh.; Jones, King's; R. Langdon-Down, Trin.; Locke, Joh.; Long, Caius; Morrell, Caius; Newstead, Christ's; Perkins, Emman.; Phear, Trin.; Schott, Trin.; H. Simpson, Joh.; H. Smith, Trin.; W. A. L. Smith, Trin.; Thornton, B.A., Christ's; Whetham, Trin.; G. Wilkinson, jun., Emman.

Women.—Class I.—L. Ackroyd, Newnham; D. Alford, Girton; A. G. Earp, Newnham; L. R. Howell, Girton; M. Kennedy, Girton.

The following have been placed in the first class in the Natural Sciences Tripos, Part II.:—Ds. Anderson, Caius (physiology); Barber, Christ's (botany); Ds. D'Arcy, Caius (physics); Ds. Francis, King's (human anat. and physiology); Fry, King's (botany); Hardy, Caius (zoology); Hutchinson, Christ's (chemistry); E. R. Saunders, Newnham (physiology).

Mr. A. C. Seward, B.A., Scholar of St. John's College, has been elected Harkness Scholar in geology and palæontology.

Mr. W. W. Watts, M.A., has been elected to a Fellowship at Sidney-Sussex College. Mr. Watts graduated in the Natural Sciences Tripos, 1881, and was placed in the first class for proficiency in geology.

At Downing College the following have been elected to minor Scholarships of £50 each open to the competition of persons not yet in residence: H. Brownsword, for physics, Manchester Grammar School; C. Swift, for chemistry, University College, Liverpool; and H. Widdicombe, private tuition, for botany. G. Dodson has been elected Foundation Scholar for Natural Science.

At Christ's College the following undergraduates have been elected to Natural Science Scholarships: A. H. L. Newstead, £60; C. Krishnau, £50; R. H. Luce, £30; H. M. Stewart, £30.

At King's College, R. C. Fry has been elected Natural Science Scholar, and G. L. Rolleston to an Exhibition of £40, and L. Falkener to £30.

At Gonville and Caius College, H. B. Brunner, Berkhampstead School, has been elected to an Entrance Scholarship of £50 for natural science.

The following Natural Science Scholars have been elected at St. John's College: H. Simpson, Hankin, Horton-Smith, Locke, Baily, Blackman, Schmitz. Turpin, B.A., has been elected Hutchinson Student for organic chemistry.

SCIENTIFIC SERIALS.

THE *Journal of Botany* continues, in its numbers for April, May, and June, Mr. J. G. Baker's Synopsis of the Tillandsieæ, and MM. Britten and Boulger's valuable biographical index of British and Irish botanists (deceased).—Students of diatoms will be interested in Mr. J. Rattray's paper on *Aulacodiscus*, in which the many and singular abnormalities of this genus of fossil diatoms are described and illustrated by a plate.—Mr. G. Massee contributes a revision of the genus *Bovista*, in which several new species of this genus of Fungi are described, also illustrated by a plate.—We have also biographies of Prof. Asa Gray, and Mr. John Smith, of Kew (the portrait of the former is not a pleasing one), and several papers on local or descriptive botany.

IN the *Botanical Gazette* for February, March, and April, we have no important papers of original research or observation such as sometimes reach us in this record of the doings of botanists in the Far West (published at Crawfordsville, Indiana). The original papers in these numbers relate almost entirely to the distribution of plants in the Western States of America, and to the description of American species.

THE number of the *Nuovo Giornale Botanico Italiano* for April contains the conclusion of Prof. A. N. Berlese's monograph of the genera of Fungi *Pleospora*, *Clathrospora*, and *Pyrenophora*, with the ten coloured plates which serve to illustrate the whole paper; and a description by Sig. C. Massalongo of a number of instances of teratology, chiefly relating to the flower. It serves further as the medium of publication of the proceedings of the Italian Botanical Society, reports being appended of a number of smaller contributions in various departments of botany.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 21.—"Muscular Movements in Man, and their Evolution in the Infant: a Study of Movement in Man, and its Evolution, together with Inferences as to the Properties of Nerve-centres and their Modes of Action in expressing Thought." By Francis Warner, M.D., F.R.C.P., Physician to the London Hospital, and Lecturer on Botany in the London Hospital Medical College. Communicated by Prof. J. Hutchinson, F.R.S.

Before proceeding to give an account of the visible evolution of voluntary movement in man, it is necessary to define the different classes of movements seen, indicating the criteria by which the observer may be guided in the examples before him.

The new-born infant presents constant movement in all its parts while it is awake, and this is not controlled by impressions from without. Graphic tracings of such movements are given This spontaneous movement in the infant appears to be of great physiological importance, and is here termed "microkinesis." It is argued that the mode of brain action which produces microkinesis is analogous to the action producing spontaneous movements in all young animals, and to the modes of cell-growth which produce circumnutation in young seedling plants. It is argued that as circumnutation becomes modified by external forces to the modes of movement termed heliotropism, geotropism, &c, so microkinesis in the infant is replaced by the more complicated modes of brain action as evolution proceeds.

The conditions of movement are then described, as seen at successive stages of development of the child, and it is shown that they become less spontaneous, and more under control of stimuli acting upon the child from without, while the phenomena termed memory and imitation are evolved.

From observations made, two hypotheses are put forward. It is suggested that when a well co-ordinated movement follows a slight stimulus, the impression produces temporary unions among the centres, preparing them for the special combinations and series of actions which are seen to follow. Such unions among nerve-centres appear to be formed when a period of cerebral inhibition, produced by a word of command, is seen to be followed by a co-ordinated series of acts. A graphic tracing indicating suspension of microkinesis to the stimulus of sight and sound is given. It is further suggested that the brain action corresponding to thought is the formation of functional unions among cells, whose outcome is seen in the movements which express the thought, or its physical representation. Properties similar to those described in brain-centres may be illustrated in modes of growth.

"Evaporation and Dissociation. Part VIII. A Study of the Thermal Properties of Propyl Alcohol." By William Ramsay, Ph.D., F.R.S., and Sydney Young, D.Sc.

In continuation of our investigations of thermal properties of pure liquids, we have now determined the vapour-pressures, vapour-densities, and expansion in the liquid and gaseous states of propyl alcohol, and from these results we have calculated the heats of vaporization at definite temperatures. The compressibility of the liquid has also been measured. The range of temperature is from 5° to 280° C., and the range of pressure from 5 mm. to 56,000 mm.

The memoir contains an account of the purification of the propyl alcohol; determinations of its specific gravity at 0°, and at 10°·72; and of the constants mentioned above.

The approximate critical temperature of propyl alcohol is 263°·7; the approximate critical pressure is 38,120 mm., and the approximate volume of 1 gramme is 3·6 c.c. The first two of these constants must be very nearly correct; the third cannot be determined with the same degree of precision.

The memoir is accompanied by plates, showing the relations of volume, temperature, and pressure in a graphic form.

Royal Meteorological Society, June 20.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—First Report of the Thunderstorm Committee. This Report deals with the photographs of lightning-flashes, some sixty in number, which have been received by the Society. From the evidence now obtained it appears that lightning assumes various typical forms, under conditions which are at present unknown. The Committee consider that the lightning-flashes may be arranged under the following types: (1) stream, (2) sinuous, (3) ramified, (4) meandering, (5) beaded or chapletted, and (6) ribbon lightning. In one of the photographs there is a *dark* flash of the same character as the bright flashes, but the Committee defer offering any explanation of the same until they get further examples of dark flashes. As the thunderstorm season is now coming on, the Committee propose to publish their Report at once, along with some reproductions of the photographs by the autotype process, in order that observers may be prepared to notice the various forms of lightning.—The cold period from September 1887 to May 1888, by Mr. C. Harding. The mean temperature for each of the nine months from September 1887 to May 1888 was below the average, whilst in the case of October there has been no corresponding month as cold during the last half century, and only three colder Aprils. In London the mean temperature for the period was only 42°·4, and there has been no similarly low mean for the corresponding period since 1854-55, which will be remembered as the time of the Crimean War, and only three equally cold periods during the last 50 years. The temperature of the soil at Greenwich at 3 feet below the surface was below the average in each month from October to April; in October and April the temperature at this depth was the coldest on record, observations being available for the last 42 years, and in November it was the coldest for 37 years.—Observations on cloud movements near the equator; and on the general character of the weather in the "Doldrums," by Hon. R. Abercromby. The author gives the results of observations made during four voyages across the equator and the "Doldrums," with special reference to the motion of clouds at various levels. Two voyages were across the Indian Ocean during the season of the north-west monsoon, and two across the Atlantic in the months of July and December. The nature of the general circulation of the atmosphere near the "Doldrums" is discussed as regards the theory that the Trades, after meeting, rise and fall back on themselves; or, according to the suggestion of Maury, that the Trades interlace and cross the equator; or, as following the analogy of Dr. Vettin's experiments on smoke. It is shown that the materials at present available are insufficient to form a definite conclusion, but details are given of the general character of the weather and of the squalls in the "Doldrums," with a view of showing what kind of observations are required to solve this important problem. The old idea of a deep Trade—with a high opposite current flowing overhead—is certainly erroneous; for there is always a regular vertical succession of the upper currents as we ascend, according to the hemisphere.

Zoological Society, June 19.—Prof. Flower, F.R.S., President, in the chair.—A letter was read addressed to the President by Dr. Emin Pasha, dated Tunguru Island (Lake Albert), October 31, 1887, announcing the despatch of further collections of natural history objects, and promising for the

Society some notes on European migratory birds observed in that country.—An extract was read from a letter addressed by Mr. E. L. Layard to Mr. John Ponsonby concerning the occurrence of a West Indian Land-Shell (*Stenogyra octona*) in New Caledonia.—Mr. Tegetmeier exhibited and made remarks on the feet of an Australian Rabbit, supposed to have acquired arboreal habits.—Prof. Bell exhibited and made remarks on a specimen of a tube-forming Actonian (*Cerianthus membranaceus*) in its tube; obtained by Mr. John Murray at a depth of 70 fathoms in Loch Etive.—A communication was read from Prof. W. Newton Parker, on the poison-glands of the fishes of the genus *Trachinus*. This paper showed the existence of glands in connection with the grooved dorsal and opercular spines of the two British species of Weever. The glands were stated to be composed of large granular nucleated cells, which are continuous with those of the epidermis. An account of the observations of previous authors, both as regards the structure and physiology of the poison-organs of these fishes, was also given.—A communication was read from Mr. H. W. Bates, F.R.S., containing the description of a collection of Coleoptera made by Mr. J. H. Leech, during a recent visit to the eastern side of the Corean Peninsula.—A second communication from Mr. Bates treated of some new species of Coleoptera of the families Cicindelidæ and Carabidæ from the valley of the Yang-tsze-Kiang, China.—Mr. J. B. Sutton read a paper on some abnormalities occurring among animals recently living in the Society's Gardens.—Prof. Bell read an account of a collection of Echinoderms made at Tuticorin, Madras, by Mr. Edgar Thurston, Superintendent of the Government Central Museum, Madras.—A communication was read from Mr. F. Moore, containing the second portion of a list of the Lepidoptera collected by the Rev. J. H. Hocking, chiefly in the Kangra District of the North-Western Himalayas. The present paper contained the descriptions of seven new genera and of forty-eight new species. An account of the transformations of a number of these species was also given from Mr. Hocking's notes.

Geological Society, June 20.—Dr. W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—On the occurrence of marine fossils in the Coal-measures of Fife, by Jas. W. Kirkby; communicated by Prof. T. Rupert Jones, F.R.S.—Directions of ice-flow in the North of Ireland, as determined by the observations of the Geological Survey, by J. R. Kilroe; communicated by Prof. E. Hull, F.R.S.—Evidence of ice-action in Carboniferous times, by John Spencer.—The Greensand bed at the base of the Thanet sand, by Miss Margaret I. Gardiner, Bathurst Student, Newnham College, Cambridge; communicated by J. J. H. Teall.—On the occurrence of *Elephas meridionalis* at Dewlish, Dorset, by the Rev. O. Fisher.—On perlitic felsites, probably of Archæan age, from the flanks of the Herefordshire Beacon, and on the possible origin of some epidosites, by Frank Rutley. The author has previously described a rock from this locality in which faint indications of a perlitic structure were discernible. In the present paper additional instances were enumerated and a description was given. The perlitic structnre is difficult to recognize, owing to subsequent alteration of the rock. Decomposition-products, apparently chiefly epidote, with possibly a little kaolin, have been found in great part within the minute fissures and perlitic cracks. The author suggested, from his observations, that felsites, resulting from the devitrification of obsidian, quartz-felsites, aplites, &c., may, by the decomposition of the felspathic constituents, pass, in the first instance, into rocks composed essentially of quartz and kaolin; and that by subsequent alteration of the kaolin by the action of water charged with bicarbonate of lime and more or less carbonate of iron in solution, these may eventually be converted into epidosites. He regarded it as probable that the rocks are of later Archæan or Cambrian age.—The ejected blocks of Monte Somma, Part I., stratified limestones, by Dr. H. J. Johnston-Lavis.

Palæontographical Society, June 22.—Annual Meeting. Dr. H. Woodward, F.R.S., Vice-President, in the chair.—The Report of the Council, presented by the Secretary, Prof. Wiltshire, stated that since the date of the last annual meeting the volume for 1887 had been issued, and that the volume for the present year was in progress. It would contain the following parts of monographs: the Stromatoporoids, Part II., by Prof. Alleyne Nicholson; the Cretaceous Echinodermata, Part I., by Dr. W. P. Sladen; the Jurassic Gasteropoda, Part III., by Mr. W. H. Hudleston; the Inferior Oolite Ammonites, Part II., by Mr. S. S. Buckman. It was stated that the arrangement by which members had been enabled to procure parts of finished monographs as well as the complete monographs, distinct from the annual volumes, had been found to work very efficiently. It was further stated that the financial position of the Society was much better than on the previous occasion. This was due in part to a grant of £50 made by the General Committee of the British Association at the Manchester meeting, and in part to the very considerable increase in the number of subscribers, which had resulted from the efforts made during the past and preceding year to bring before geologists, palæontologists, and all interested in science, the work which was carried on by the Society. If the present improvement could be maintained, there need be no fears for the future.—Sir R. Owen was re-elected President; Mr. Etheridge, Treasurer; and Prof. Wiltshire Secretary. Messrs. W. E. Balston, C. J. A. Mëyer, G. H. Morton, and W. P. Sladen were elected members of the Council, in the place of Messrs. S. S. Buckman, J. Evans, C. H. Gatty, and W. C. Lucy, who retire by rotation.

PARIS.

Academy of Sciences, June 25.—M. Janssen, President, in the chair.—On the canals of the planet Mars, by M. Fizeau. The various circumstances connected with these appearances, as lately described by MM. Perrotin and Schiaparelli, suggest a strong analogy with certain phenomena of glaciation—parallel ridges, crevasses, rectilinear fissures often of great length and at various angles—observed in the regions of large glaciers in Switzerland and especially in Greenland. This leads to the hypothesis of a vast development of glaciation on the surface of Mars, where, the seasons being relatively longer and the temperature much lower, the conditions must also be more favourable than on the earth for these manifestations. The reading of the paper was followed by some remarks by M. J. Janssen, who gave a guarded assent to M. Fizeau's "very ingenious and very beautiful" theory.—On the vapour-density of the chloride of aluminium, and on the molecular weight of this body, by MM. C. Friedel and J. M. Crafts. The recent experiments of MM. Nilson and Pettersson tended to show that this substance should receive the formula $AlCl_3$ rather than the double formula Al_2Cl_6 proposed by MM. Sainte-Claire and Troost. The fresh researches of MM. Friedel and Crafts, undertaken to settle the point, lead to the conclusion that the density corresponds to Al_2Cl_6, which would accordingly represent the molecular weight of the chloride of aluminium. The experiments of MM. Louïse and Roux on methyl and ethyl aluminium are in harmony with this inference.—Progress of the Roscoff and Arago Laboratories, by M. de Lacaze-Duthiers. Both of these important biological stations have lately been inspected by the author, who is able to speak most favourably of their present state. Zoologists will find concentrated at Banyuls during the winter and at Roscoff in summer all the conditions best adapted for the study of the lower forms of animal life.—Some remarks relative to the representation of irrational numbers by means of continuous fractions, by M. Hugo Gyldén. From the points here discussed flows a thesis of great importance connected with the convergence of certain trigonometric series employed in the calculation of perturbations. The thesis is thus worded: The probability of finding a value for a beyond a given limit is in inverse ratio to the number expressing this limit.—On the degrees of oxidation observed in the efflorescing compounds of chromium and manganese, by M. Lecoq de Boisbaudran. In this first paper on the subject the author deals mainly with the carbonate of lime in combination with an oxide of chromium (or chromate of ammonia), and highly calcined in the air. He shows that chromium produces with lime a fluorescence which seems to present no analogy with those yielded by it in combination with alumina, gallina, or magnesia.—On orthogonal substitutions and the regular divisions of space, by M. E. Goursat. The divisions here determined may be connected with the regular figures of space of four dimensions. Thus may readily be found the six regular figures discovered by Stringham. But the question may be pushed further, and, by following Poinsot's method, in space of four dimensions the existence may be shown of regular figures analogous to the regular starred polyhedrons of space of three dimensions. These results, here merely indicated, will be fully developed in a memoir which will shortly be published.—On a theorem of Kummer, by M. E. Cesaro. This is in connection with a recent paper by M. Jensen, who is stated to defend himself from inaccuracies of which he was not accused. In the author's communication of April 16, nothing was questioned except the *novelty* of M. Jensen's theorem, which does not differ essentially from that of Kummer, as modified and completed by Dini in 1867.—On the hydrochlorates of trichloride of antimony, of trichloride of bismuth, and of pentachloride of antimony, by M. Engel. The researches here described fully confirm the existence of these bodies, which are described as well-defined salts that may be easily isolated. Like all the other hydrochlorates of chloride hitherto prepared, they all contain water of crystallization, and there are in each case at least two molecules of water for each molecule of hydrochloric acid fixed by the chloride.—On the reproduction of phenacite and the emerald, by MM. P. Hautefeuille and A. Perrey. The conditions are described under which the authors have effected the synthesis of two substances whose properties are identical with those of natural phenacite and the emerald. The analysis of the artificial emerald yielded silica 67·7, alumina 19·6, and glucine 13·4, which are nearer to the calculated proportions than those given for the composition of most natural emeralds. The analyzed crystals, whose density was 2·67, were colourless; but greenish-yellow and green crystals were easily obtained—the former by the oxide of iron, the latter by the oxide of chromium.

BERLIN.

Physiological Society, June 8.—Prof. du Bois-Reymond, President, in the chair.—Prof. Kossel spoke on a new constituent of tea. Inasmuch as the presence of caffein in tea does not suffice to explain its physiological action, he had examined it for other bases, and found in the leaves of tea, in addition to adenin, a new well-characterized base whose composition is $C_7H_8N_4O_2$, to which he has given the name of theophyllin. Theobromin and paraxanthin have the same chemical composition as theophyllin, but the latter differs from the former by a series of well-marked chemical reactions. One question of special interest was as to the constitution of the new base, which belongs to that class of substances known as the xanthin-bodies. Fischer has shown that xanthin yields alloxan and urea when oxidized; and, similarly, it is known that theobromin is dimethylxanthin, yielding, by oxidation, methylalloxan and methylurea; as also that caffein is trimethylxanthin, yielding, by oxidation, dimethylalloxan and monomethylurea. The question hence arose as to the constitution of the new base, which, since it is isomeric with theobromin, is also presumably a dimethylxanthin. Since the speaker was in possession of so limited a quantity of the substance that he could not proceed to oxidize it, he proceeded by a different method, and introduced a methyl group into the molecule of theophyllin: on performing this experiment he obtained caffein, from which it must be concluded that theophyllin contains one methyl group united to a residue of urea, and one to a residue of alloxan, and has therefore a constitution identical with that of theobromin. It still remains to investigate the physiological action of the new base.—Dr. Will spoke on the alkaloids of the Solanaceæ, of which at present only atropin, hyoscyamin, and hyoscin are known as distinct substances with reference to their mydriatic action. The first two of the above are of special interest, as possessing the same chemical composition ($C_{17}H_{23}NO_3$), but differing as regards their melting-point, the salts which they form with gold, and their specific rotatory powers. It had been noticed long ago that sometimes much atropin and but little hyoscyamin, and, *vice versâ*, much hyoscyamin and but little atropin, is obtained from the roots of Belladonna. This difference in the relative amounts of the two substances obtained was noticed when portions of the same sample of roots were treated in the same way; as the result of which the chemical factory of Schering had requested the speaker to investigate the cause of this difference in the relative amounts of the several products. The first fact which he determined was, that when hyoscyamin is heated to 109° C.—that is to say, to a temperature slightly above its melting-point—it changes into atropin. This is, however, of no significance in the preparation of the alkaloids, as carried on in a factory, inasmuch as no such temperatures are employed. Dr. Will further found that, when a few drops of alkali are added to a solution of hyoscyamin which possesses strong rotatory powers, in a few hours the rotatory power is lost, and the solution no longer contains hyoscyamin, but atropin. According to this, during the extraction of Belladonna roots in the factory, the amount of hyoscyamin which may have become converted into atropin is dependent upon the time of action and the concentration of the alkaline solution employed in the process: by treatment with alkali, the whole of the hyoscyamin can always be converted into atropin. The fact that, by the extraction of the roots of Hyoscyamus, onl hyoscyamin and no atropin is obtained, was explained by th speaker as being due to the employment of ammonia in th process, which has only a feeble power of converting the on alkaloid into the other. The speaker intends to employ thi conversion of hyoscyamin into atropin, which is measurable b means of change in rotatory power, to the determination of th combining affinities of the alkalies. Dr. Will is inclined t believe that relations similar to the above exist in the case o quinine and cinchonine, which are also obtained in varying rela tive amounts from the bark.—Dr. Koenig gave an account o some experiments, undertaken at his suggestion by Isaacksen with a view to testing Holmgren's statement that very smal coloured dots can only be seen as one of the primary colours o the Young-Helmholtz theory—namely, red, green, or violet. This statement was not, however, confirmed when the necessar precautions were taken, and it was found that small dots of an colour, even yellow and blue, were perceived as possessing thei own objective colour; this had also been observed by Hering Isaacksen had, further, investigated the power which the ey possesses of distinguishing between minute dot-like light which are so small that their image on the retina only falls o one cone, and found that it was as fully developed as for th colours of large surfaces.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

Chemical Problems: Grabfield and Burns (Heath, Boston).—The Move ments of Respiration and their Innervation in the Rabbit: Dr. M. Marck wald, translated (Blackie).—Natural History and Epidemiology of Cholera Sir J. Fayrer (Churchill).—The Photographer's Note-book and Index: Sir D Salomons (Marion).—Short Lectures to Electrical Artisans: J. A. Fleming second edition (Spon).—Whence comes Man; From Nature or from God? A. J. Bell (Isbister).—*Challenger* Expedition Report, vols. xxiii., xxiv. Parts, and xxv., Zoology (Eyre and Spottiswoode).—Annual Report of th Geological and Natural History Survey of Canada, vol. ii. 1886 (Dawson Montreal).—Another World, or the Fourth Dimension: A. T. Schofiel (Sonnenschein).—Changes of Level of the Great Lakes: J. K. Gilbe (Washington).—The Construction and Maintenance of School Infirmaries an Sanatoria (Churchill).—Electricity *versus* Gas: J. ELECTRICITY AND MAGNETISM.

A Treatise on Electricity and Magnetism. By E. Mascart and J. Joubert. Translated by E. Atkinson. Vol. II. (London: De La Rue and Co., 1888.)

THE English translation of the second volume of the valuable work of MM. Mascart and Joubert is a welcome addition to the class, none too large, of really substantial English books on electricity. We have already directed the attention of the readers of NATURE to the first volume of this work; and we took occasion to point out that in their exposition of the subject the authors follow very closely the general methods of Clerk-Maxwell. That they do so is a great advantage for the English student; because it enables him, without breach in the continuity of his studies, to use Mascart and Joubert as a commentary upon Maxwell, who is often by no means easy reading. The French work is also supplementary to Maxwell, for writers avoid as much as possible the purely theoretical side of electrical science, and treat electrical phenomena, more especially in their second volume, as subjects of observation, and, above all, of measurement. This volume, which is now before us, is, in fact, an epitome of all the wisdom in exact electrical measurement which has been gained during a period of extraordinary activity in that field. This period began with the researches of Gauss and Weber; and may perhaps be said to have culminated in the great series of determinations of the absolute units which were made about the time of the Congress of Electricians at Paris in 1884. The prominent part taken by MM. Mascart and Joubert in this work has well fitted them to record with precision the details of the leading methods by which it was accomplished, and it would be hard to refer the student of electrical science to an authority on electrical measurement at once so clear and precise in detail, and, with a few small and evidently accidental exceptions, so manifestly candid and fair, as the second volume of the treatise of Mascart and Joubert.

The space at our disposal in the pages of NATURE allows us to give but a brief summary of the contents of this volume. Part I. deals with the auxiliaries of electrical measurement, such as the measurement of angles, of the periods and amplitudes of oscillations, of couples, and of such properties of circular currents as are important in the construction of galvanometers and other electrical instruments. As an example of the care with which the subject is treated, we may refer to the discussion, in §§ 659, 660, of the power of a telescope, and of the relation that ought to subsist between the dimensions of a graduated circle and of the telescope with which it is associated. The conclusion of this discussion is marred in the English version by inadequate translation. Thus, for example, "un cercle de ce diamètre [80 cm.] devra donc être associé à une lunette de 16 centimètres d'ouverture," does not mean "a circle of this diameter is therefore comparable with a telescope of 16 cm. aperture." The meaning is, that, to get the full use of the circle, a telescope having an objective lens of 80 cm. aperture is required; and that a more powerful one is unnecessary.

Part II., which is the kernel of the volume, describes the various electrical measurements as they are carried out in practice. There are chapters on electrometry, and on measurement of current, resistance, electromotive force, capacity, constants of coils, absolute resistance, and the fundamental velocity, *v*. The methods are described in great variety and with great detail. They are illustrated by giving not only the old classical results, but also by means of the most recent examples. Nothing is attempted like the exhaustive catalogue of results, good, bad, and indifferent, which makes Wiedemann such an invaluable book of reference. Experimental results are given simply as part of the exposition of the methods by which they are obtained. It is probably for this reason that the authors make no mention of the valuable experiments on dieletric strength recently made by their fellow-countryman, Baille.

Part III. is devoted to magnetic measurements, and is excellent so far as it goes. It is by no means so exhaustive as the purely electrical part; and, probably for that very reason, will be found to be lighter reading for the tyro in electricity and magnetism; to such we commend more especially the parts relating to the determination of so-called magnetic poles and to the magnetism of feebly magnetic and diamagnetic bodies, subjects which are very frequently imperfectly understood or inadequately expounded in current text-books.

Part IV., which is called a complement, deals with industrial applications, and contains a table of numerical constants. The table of constants gives full references to the sources of such information as it contains, and will be found most useful. The part that deals with industrial applications is to our thinking the least satisfactory part of the book; not because there is any want of clearness or soundness in it, but because it is too short and too scantily illustrated by references to practical cases to give the student any real idea of the problems that surround the electrical engineer.

In describing the various methods of electrical measurement the authors are, on the whole, very sparing of criticism. They seem to assume that they are addressing an audience fitted to draw their own conclusions from the facts put before them. Occasionally the weak points of the methods used by various experimenters are pointed out, but the authors never indulge in that species of criticism which consists in treating a fellow-labourer and all his productions with indiscriminate scorn because the critic has discovered some microscopic oversight, or believes that he has wrung one more decimal place from reluctant Nature.

There are one or two little points which might be amended in a future edition. For example, the elegant method of discussing resisted motion by means of the equiangular spiral, given in § 682, should be attributed to its author, Prof. Tait. The use of the fish-back galvanometer-needle (*i.e.* a needle made up of a number of separate parallel needles) was not an invention of M. Deprez, at least not an original invention; for the writer used, more than twelve years ago, a galvanometer fitted with a needle of this sort, which had been constructed for the B.A. Committee of 1867. Who the inventor was, is doubtful; but probably he took his idea from the laminated magnets constructed by Jamin and others. Perhaps the most serious historical oversight is made in § 1274, where, in speaking of the graphical characteristic of a dynamo, language is used which would lead the reader to infer that this important method in the theory and practice of electrical engineering was introduced by M. Marcel Deprez, the fact being that it was first introduced, fully explained, and actually used by Dr. Hopkinson in 1879.[1] What M. Deprez did, was, we believe, simply to give a name to Hopkinson's curve, and to further develop its applications. It would be easy to correct, in footnotes or otherwise, these and a few similar small blots on a work which is, in most respects, remarkably fair and cosmopolitan in its history.

Regarding the work of the translator, we can, on the whole, speak very favourably. There are, however, passages here and there which are so inadequately translated that they suggest the idea of an inferior assistant not always sufficiently overlooked. Compare, for example, the following piece of the original with the accompanying translation:—

"Si la loi était générale, on en conclurait, pour le cas de deux plateaux parallèles, que la production de l'étincelle correspond toujours à une même valeur de la densité électrique et, par suite, de la force électrique et de la pression électrostatique, ou, dans les idées de Maxwell, à un même état ou une même énergie spécifique du milieu interposé."

"If the law was general, we should conclude, for the case of two parallel plates, that the production of electricity almost represents the same value of the electrical density, and therefore of the electrical force and the electrostatic pressure, or, as in Maxwell's views, to the same condition or the same specific energy of the interposed medium."

It will be seen that the English passage is not a translation of the French, is not English, and means nothing. We mention this, by far the worst, case of loose translation that we have noticed, to draw the attention of the English editor to the need there is for revision. Such corrections as are absolutely necessary might be given on a fly-leaf; and, in order to help, we mention a few things that we have noticed. Some are misprints, some wrong, some merely doubtful.

P. 39, "compass of horizontal intensity"?

P. 41, "observations" (oscillations?)

P. 48, "collate" (collect?)

P. 50, "bodies of easy construction"?

P. 237, "combine the experiment"?

P. 293, "but they are not sufficiently so, &c."?

P. 557, "*residues* of the Leyden jar"?

P. 577, "induced *charges*" (décharges induites)?

P. 578, "to *make the constant* of the ballastic galvanometer" (faire la tare: why use tare? Tare is English).

P. 878, "regulation of a galvanometer" (tarage d'un galvanomètre)?

Notwithstanding minor shortcomings, this English translation of the work of MM. Mascart and Joubert will be of great use to English readers; and we hope that it will not be thought that, by calling attention to inaccuracies here and there, we mean to depreciate the labour of the editor, or to undervalue the debt which the English scientific public owes him for rendering more accessible one of the most important electrical treatises of the day.

G. C.

SYNOPTICAL FLORA OF NORTH AMERICA.

Synoptical Flora of North America: the Gamopetalæ. A Second Edition of Vol. I. Part 2, and Vol. II. Part 1, collected. By Asa Gray, LL.D. Large 8vo. 480 + 494 pp. (Washington: Published by the Smithsonian Institution, 1888.)

THE first feeling which the sight of this book reawakens in the mind is one of deep regret that Prof. Asa Gray did not live to carry out the plans he had entertained so long for an elaboration of a complete flora of Temperate North America upon one uniform plan. A work of this scope was planned by Dr. Torrey and himself when he was quite a young man, and the first part appeared as long ago as 1838. It was soon found by the authors that it was impossible to identify satisfactorily the plants which had been named by their predecessors without studying the European Herbaria; and in order to do this Dr. Gray spent a year in Europe in 1838–39. Another instalment, which extended to the end of Polypetalæ, was published in 1840, and the remainder of the first volume, extending to the end of Compositæ, in 1842. Then Dr. Gray accepted the post of Fisher Professor of Natural History in the University of Harvard, and what with teaching and herbarium work, and the preparation of the successive five editions of his "Flora of the Northern United States," and the elaboration of the new collections that poured in as fresh territories were explored and settled, his time was fully occupied for thirty-five years. In 1878 he returned to the more comprehensive work, and in that year published the first part of the second volume, which includes the remaining orders of Gamopetalæ, from Goodeniaceæ to Plantaginaceæ. In 1884 he issued a revised edition of the part devoted to the Compositæ and small allied orders. The work we have now before us is a reprint of the whole of the Gamopetalæ, with two supplements, embodying additions and corrections up to the end of 1885. Although the title-page bears the date of 1888, it was really issued, as the secondary title-page indicates, in January 1886, and we have had it in use at Kew for a couple of years. The present volume, therefore, covers the central third, brought up to date, of the complete undertaking as planned; and at the beginning the Polypetalous Dicotyledons are still left as they stood in 1840, except for the most useful bibliographical index, brought up to date, which Dr. Sereno Watson issued in 1878; and the Incompletæ and Monocotyledons, to which Dr. Watson has happily devoted special attention during many years, have still to be dealt with.

The flora of Temperate North America contains about the same number of species as that of the whole of Europe, but of course the orders are to a certain extent different, and others enter in the two floras in very different proportions. In the present work there are described 3521 species of Gamopetalous Dicotyledons, of which all but 162 are indigenous. They fall under 562 genera, of which 520 are native. The American Compositæ alone, 1636 species, far more than outnumber the whole Phanerogamic flora of Britain. Next to Compositæ come Scrophulariaceæ, represented by 367 species and 38 genera. Of Hydrophyllaceæ, an order nearly restricted to North America, there are 129 species and 14 genera; of Polemoniaceæ, another nearly endemic order, there are 133 species. The more tropical character of the North American, as compared with the European, flora, is shown by the presence of 44 non-stellate Rubiaceæ, 9 Sapotaceæ, 97 Asclepiadaceæ, 6 Bignoniaceæ, and 41 Acanthaceæ. To get such a large number of plants worked up by such a model systematist as Dr. Gray is an enormous boon to all species botanists. A great many of the species are here described for the first time; and a still larger proportion have only been previously noticed in scattered unclassified papers. A large number of the best-known North American plants cultivated in our gardens belong to Gamopetalæ; and to have such genera as Aster, Solidago, Helianthus, Pentstemon, Phacelia, and Gilia, put in order and brought up to date will be a great saving of time and trouble, and make the book essential, not only to botanists, but to all owners of gardens who wish to understand the characters, affinities, and geographical distribution of the plants they grow.

In arranging their material the authors of the four great recent descriptive local floras have followed four different plans. In Bentham's "Flora Australiensis" there is, under each genus, an initial analytical key, in which each species is distinguished, and afterwards a single detailed description of each species and its varieties. The 8500 species of the Australian flora, described after this plan, fill seven volumes of from 500 to 800 pages each. In Boissier's "Flora Orientalis" the initial key only goes down to the sections, and there is a less detailed single description given of each species. The number of species is about 10,000, and the whole work runs on to five large volumes of about 1000 pages each. In Sir J. D. Hooker's "Flora Indica" there is no initial key, but sub-genera and groups are briefly characterized, and under each species is given both a compact diagnosis and brief description. Under this plan the 10,000 Dicotyledons of India fill five octavo volumes of 700 to 800 pages each. Dr. Gray gives no initial key, more detailed characters of sub-genera and groups, and under each species a single short description. Under this plan the 3500 Gamopetalæ fill a book of 970 larger pages. It is an omission, we think, that Dr. Gray has not numbered his species, for, in referring from the book to the herbarium and back again, such numbers are a very useful guide. Mr. Bentham, Sir J. D. Hooker, and Dr. Gray all three adopt the same comprehensive idea of what constitutes a species, and use substantially the same orders and genera, and the same plan of nomenclature; and it is a very great convenience in herbarium work that these three great floras have been treated upon one uniform system.

Our best sympathies are with the American botanists in the great loss they have sustained. In securing such a competent assistant as Dr. Sereno Watson, Dr. Gray was very fortunate, and we trust that the material for the two other volumes is in such an advanced state of preparation that they may be published under his editorship before long. We European botanists have great reason to thank the managers of the Smithsonian Institution for their liberality in granting funds for the book. What a boon it would be if we could have a general flora of Europe planned upon the same lines; but with all our great Universities and Herbaria this does not at present seem at all likely.

J. G. BAKER.

HYDRODYNAMICS.

Treatise on Hydrodynamics. Vol. I. By A. B. Basset. (Cambridge: Deighton, Bell, and Co. London: George Bell and Sons. 1888.)

THIS book deserves to be most warmly received by all who are interested in this branch of mathematics, in which remarkably rapid progress has been made of late years. For some time past a constant and familiar acquaintance with the Proceedings of learned Societies has been necessary to enable students to keep abreast with the subject; and the author has performed real service in incorporating in his work many important results and memoirs.

This volume, which is to be followed by a second, contains the general equations of motion, with the auxiliary discussions of vortex and irrotational motion, and also the theory of motion of solids in a fluid, in which both the hydrodynamical and the dynamical effects of the motion are very fully discussed. The chapter on the equations of motion is noticeable for the introduction of Clebsch's transformation, proving the permanency of vortex lines and vortex sheets, and for the application of the principles of least action and energy. Students are apt to lose sight of general dynamical principles in the not inconsiderable difficulties of pure analysis that attend this subject; and it is well they should be aided to bear in mind that their symbols are after all intended to represent physical phenomena, while it adds considerably to the interest of the subject to exhibit its analogies with kindred physical principles. But it is to be regretted that in this chapter the author has not removed the obscurity which arises from the fact that the equations of motion can be obtained in the same form by either a Lagrangian or an Eulerian method. The device of endowing each particle of fluid with co-ordinate axes, all its own, marks the first method; the observation of fluxes at a certain point of space is the distinguishing feature of the second. To identify the results thus obtained (as *e.g.* in the equations of motion in spherical co-ordinates) is justifiable, but will certainly lead to much misapprehension at the outset.

A chapter on images and doublets is useful as collecting together what must otherwise be introduced in a random manner. The discussion of motion in two dimensions is as complete as the limited number of cases that are soluble will allow; several new cases, not previously found in the text-books, illustrate the increasing difficulty of the analysis. In dealing with discontinuous motions the author follows Kirchhoff, beyond whose work on this question it seems impossible to advance.

The second half of the book, treating of the motion of solids in a fluid, is singularly interesting, and contains the last contributions to the dynamical theory, which are due to the author himself. These are marked by great generality of treatment and power of analysis, but we fear the complexity of the results will prevent their being generally appreciated.

In dealing with the velocity-potential due to the motion of an ellipsoid, it would appear that the most direct and general method of obtaining the result in every case is to form Laplace's equation in ellipsoidal co-ordinates; instead of this the author has recourse to formulæ in the theory of attraction, which need modification to suit each special case.

A chapter on the motion of two spheres indicates the attention given to this problem of late years, and may also serve as a warning of its hopelessness. The anticipations of its yielding an explanation of magnetic phenomena, to which the first experiments by Bjerknes gave rise, have been dissipated by the exhaustive mathematical treatment it has received.

The excellence of this work leads us to look forward with great interest to the publication of the second volume, which will deal with fresher and more suggestive portions of the subject; and the two volumes together will prove of very great use to every student. The words on the title-page, "with numerous examples," strike us as below the dignity of a subject like hydrodynamics. The book will certainly be appreciated for its own merits even more than for its examination usefulness, to which aim too many books conform.

OUR BOOK SHELF.

Sierra Leone; or, the White Man's Grave. By G. A. Lethbridge Banbury. (London: Swan Sonnenschein, Lowrey, and Co., 1888.)

THE author of this book explains that he does not offer it as "one of travel over unknown ground" or "as one of dangerous adventures and hardships." His aim simply is to bring before his readers a description of an Englishman's life in "the most interesting but deadly colony of Sierra Leone." He has done his work well, and the book will be cordially welcomed by all who have any special reason for wishing to obtain clear and accurate information about this part of the West African coast. The volume consists chiefly of letters written while Mr. Banbury was at Sierra Leone, and has therefore a freshness and vividness which it would have been hard for him to match in a more elaborate and formal work. The most valuable chapters are those in which he sets forth the impressions produced upon him by the natives, in whose ideas and customs, as here depicted, there is an odd mixture of Christianity and the lowest forms of paganism. Mr. Banbury has a strong belief in the power of education to improve the character of the native population, and he urges that more strenuous efforts should be made for the establishment of proper schools. It is tolerably certain that if permanent good cannot be done to the colony by this means there is no other way in which real progress can be secured, for, as Mr. Banbury points out, the unhealthiness of the climate prevents any large increase of the number of European settlers.

Nature's Fairy-Land: Rambles by Woodland, Meadow, Stream, and Shore. By H. W. S. Worsley-Benison. (London: Elliot Stock, 1888.)

THIS book consists of a series of papers selected from a considerable number which have appeared in various periodicals. The author has a clear, pleasant style, and his vivid descriptions and explanations are well adapted to awaken in the minds of young readers a genuine interest in various aspects of scientific truth. The volume opens with an attractive paper on "The Journeyings of the Rain Drops," and this is followed by papers entitled "From Root to Flower," "Out Among the Gorse," and "Companions of the Corn." These three papers serve as an introduction to other chapters on plant-life. There are also interesting essays on such subjects as shells and shell-builders, spiders, and the nests of fishes.

Lessons in Elementary Mechanics. By W. H. Grieve, P.S.A. (London: Longmans, Green and Co., 1888.)

THE second stage of mechanics is alone dealt with here, and throughout, the author has rendered the various forces which produce motion, together with the laws which regulate those forces, in a clear and simple style; the illustrations are numerous, and are specially adapted to an elementary course. The work is suited to the requirements of the second stage of the revised code, and the arrangement of the chapters is the same as that in the Syllabus of Instruction adopted by the London School Board. The examples at the end of each chapter are instructive and well chosen, and the book concludes with a series of examination papers and results to the numerical questions.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Photography of Lightning.

So much interest is being taken at the present time in obtaining photographs of lightning flashes, that perhaps some one would be willing to take the necessary trouble, and use a moving camera. A camera revolving or vibrating at any ordinary pace would probably give each single flash unaltered, but it might analyse multiple and complex flashes into their constituents.

The eye is so easily deceived as to what is really happening in these sudden effects that very erroneous views may easily be formed, and indeed are in some quarters now prevalent.

Whether it is better to make the camera revolve as a whole, or only the sensitive plate, or whether a revolving mirror should be used with a stationary camera, are questions for experience to decide.

One good method, if not too troublesome in practice, would be to arrange a double camera, with component axes parallel, so as to photograph the same flash in both halves, but with the sensitive plate of one fixed, of the other rapidly revolving. Appearances really due to succession in time could be then easily distinguished, and might be capable of interpretation.

July 10. OLIVER J. LODGE.

Micromillimetre.

I AM glad that the Council and Fellows of the Royal Microscopical Society have seen their way to the adoption of the word *micron*, but the letter in which Mr. Crisp announces this decision to you is not, I think, calculated to give a correct impression of the circumstances under which it was taken.

Firstly, I need hardly say that I did not take exception to the word *micromillimetre*, but to its use as equivalent to the thousandth of a millimetre.

In the next place, I wrote to the Secretaries of the Royal Microscopical Society on behalf of the Council of the Physical Society, of which no mention is made by Mr. Crisp.

Thirdly, the proposal of the Council of the Physical Society was that the word *micron* should be adopted.

Lastly, I am myself quite in favour of this course, and in fact moved its adoption by the Physical Society.

The word *micromētre* must in accordance with the rules of the B.A. Committee be a possible alternative just as a *cubic decimetre* is alternative to a *litre*, and I think the disadvantage of the multiplication of special names not based on a uniform system is nearly as great as that of the possible occasional confusion between micromētre and micrometer. This is however a little matter as compared with the use of *micromillimetre* in two different senses, and the official sanction of *micron* by the French authorities (of which I was not aware when I originally wrote to you) is quite sufficient to turn the scale in its favour.

As some of your readers may not have seen the previous correspondence, will you allow me in conclusion to state that it is now generally agreed,

(1) That the thousandth of a millimetre shall be called a *micron* and denoted by μ.

(2) That the millionth of a millimetre shall be called the *micromillimetre* and denoted by $\mu.\mu$.

ARTHUR W. RÜCKER.

Distribution of Animals and Plants by Ocean Currents.

I beg to forward you herewith some extracts from a letter just received from Port Elizabeth, South Africa, which, I think, cannot fail to interest your readers in connection with Darwin's theory of the distribution of animals and plants in some cases by ocean currents. My correspondent writes :—

"About the beginning of the year 1887 the attention of the public of Port Elizabeth was aroused by finding a quantity of pumice-stone washed up upon the shores of the bay, showing volcanic action. Some of the pieces were covered with barnacles of a few months' growth, and others appeared as though a mass of vitrified matter had been poured upon them. At the same time, shipmasters stated that they had seen large masses floating upon the sea as they approached the east coast of Africa. Strange fish also made their appearance in our waters, and, among the number, two large specimens of the ox-ray species were found washed up upon the rocks. But more remarkable was the discovery of four venomous sea-snakes about 18 inches long, the bodies marked black above and yellow below, answering the description of the *Pelamis bicolor* usually to be found about the coasts of Sumatra, Java, and the adjacent isles, and which must have followed the floating debris. One of these snakes was still alive when found, although it did not long survive, and one of the others was in a sufficient state of preservation to be sent to the Museum. What will prove more interesting still, is the discovery of a large seed resembling a cocoa-nut, which was picked up about the same time, of which Mr. Russell Hallack, of Port Elizabeth, gives the following description :—

"'About the latter end of 1886 a large husky fruit was picked up. It resembled a square cocoa-nut of 4 inches cube, not quite so deep as broad and long. Inside this husk, which was more cork-like than fibrous, was a solitary nut, about $1\frac{3}{4}$ inch round, melon-shaped, with fluted outside, covered with a coating resembling potato-peel. This nut had been bitten by the boy who found it, but whether the taste was not to his liking, or for some other reason, he was persuaded to give the remains to the gardener of the north-end park, who planted it. In due time the shoot came up like a potato-plant with small leaves. The plant is now about 4 feet high, and the small leaves have developed into grand foliage 20 inches long by 7 or 8 broad. It is supposed to be the *Barringtonia speciosa*, a native of the East Indies. A smaller variety, the *B. racemosa*, is said to exist in Natal and the east coast of Africa, but is easily distinguished from this by the smallness of its fruit. The *B. speciosa* belongs to the myrtle tribe, but differs from the ordinary type in having this large, one-sided, corky husked fruit; it is one of the handsomest of its tribe, and in the Moluccas attains the height of 40 or 50 feet, with a circumference of 10 to 14 feet. It is generally found near the sea.'"

The suggestion is that this nut, as well as the snakes, the strange fish, and the pumice-stone, are all relics of the great Krakatão eruption in 1883, and that they had drifted about till the beginning of 1887, till thrown upon the coast of South Africa. If this be really the case, the tenacity of life in the snakes and the nut is truly remarkable, and, as my correspondent adds: "Surely some of this debris must have been deposited on the island shores visited by these currents, and if we could only become acquainted with the date of their appearance upon each, some idea might be formed as to the course taken by these plants, &c., in their journey to Southern Africa."

I find, by a reference to the back numbers of Nature, that the pumice has been traced to the east coast of Africa, leaving portions on various islands *en route*, and that some of it was timed to reach the west coast of America at Panama in 1886; but nowhere do I find any notice, except that given above, of animal or vegetable debris accompanying the masses of pumice. Perhaps the publication of these interesting facts may call forth similar observations from some of the Pacific Islands.

A. W. Buckland.

Watches and the Weather.

My neighbours, Messrs. Jacob and Ross, watchmakers, often tell me their experiences in the breaking of mainsprings.

Unreflecting people fancy they have broken the spring by over-winding, or in other words have drawn asunder a piece of steel by the force of finger and thumb.

The springs of course break through a subtle molecular change produced in the steel by atmospheric causes: they usually fly asunder a few hours after being wound, at 3 or 4 o'clock in the morning. Many watches and clocks come to the workshops for new springs after a frost, but not until a thaw has set in; still more come after thunderstorms.

This morning a clock spring was taken out of its box, which had overstrained itself at one moment into seventeen pieces, there was a complete fracture in each coil along a radial line from the centre. Some time back one was found with three such radial lines of fracture.

Of course this subject is not new, but it gains by recorded experiences.

W. B. Croft.

The College, Winchester, July 9.

Preserving the Colour of Flowers.

I should be greatly obliged if some of your readers would inform me how to preserve the colour of those flowers prone to fade during and after pressing.

In a local paper I saw an extract from the *Pharmaceutical Journal*, in which salicylic acid was recommended. I have tried it both as powder and in solution in spirit; in either case it had a great tendency—except in the case of yellow flowers—to change the colour to either a bright scarlet or to a light brown.

A. W.

[There is no difficulty in preserving the colour of yellow flowers if they are properly dried by the ordinary method, *i.e.* in absorbent paper, changed at the end of the first day, and once or twice afterwards. It is very difficult to prevent such plants as Pedicularis, Bartsia, and Melampyrum turning black. See an account of a plan recently tried in Germany by Schönland, in *Annals of Botany*, vol. i. p. 178, 1887.—J. G. Baker.]

THE LIFE STATISTICS OF AN INDIAN PROVINCE.

SOME years ago, in this journal (vol. xxix. p. 338), I published a short article on the intimate relations which subsist between meteorological conditions and the statistics of death and crime in India. In this it was incidentally mentioned that, imperfect as they were, the vital statistics of the North-West Provinces and Oudh were at that time more to be depended on than those of any other province in India, thanks to the unremitting attention paid to the subject of registration by the late Sanitary Commissioner, Dr. Planck; and though they have not sensibly improved since 1884, but perhaps rather fallen off in accuracy, the birth and death registers of these provinces are still undoubtedly better than any others in India embracing an equal population.

As ten complete years have now elapsed since the amalgamation of the two provinces, which together contain a larger population than any European country except Russia, and as similar statistics are not at present obtainable from any other Oriental country but India, it may be of interest to compare some of the conditions of life revealed by them with those obtaining in the more favoured countries of the West. That India has a high death-rate, owing to the unhealthiness of the prevailing climatic conditions and imperfect sanitation, as well as to the low vitality of the mass of the people consequent upon superabundant population and insufficient food, is universally understood; but there is no proper appreciation of the marvellous recuperative power of a population among whom prudential restraints on increase are unknown, and where almost every woman has been married in childhood, and commences to bear children at the age of fourteen or fifteen years. It may be said with almost absolute truth that there are not only no old maids in India, but no unmarried women above the age of puberty, except the unfortunate class of Hindu widows of the higher castes, who are not permitted to marry again; but though this class appeals in many ways to our sympathies, it is of very slight importance from the point of view of the increase of population, the widows of child-bearing age amounting to only 9 per cent. of the total number of females of the same age—a proportion which compares very favourably with that of widows and spinsters in England. This wonderful power of rapid recovery after decimation by famine or pestilence will be fully exhibited in the tables given below.

The registration of deaths was in regular operation for several years, both in the North-West Provinces and in Oudh, before the two were united under one administration in 1877. That of births was first introduced generally in 1879, though it had been tentatively commenced in municipalities and cantonments some time previously. We have therefore now (February 1888) ten complete years' death statistics for the united provinces, of a fairly uniform degree of accuracy, and nine years' registers of births, decidedly improving in completeness and accuracy for the first five or six years. The births for the first year of the ten—1878—may also be approximately arrived at by a proportionate computation from those registered that year in municipalities. The total number of births of each sex, registered in each of the ten years, was as follows:—

Year.	Males.	Females.	No. of Males to 100 Females.
1878	667,975*	545,285*	122.50
1879	669,921	555,911	120·51
1880	747,953	642,826	116·34
1881	948,191	831,282	114·06
1882	875,616	780,543	112·18
1883	950,932	850,469	111·81
1884	1,015,699	915,262	110·98
1885	957,672	861,609	111·15
1886	874,099	785,433	111·28
1887	902,844	805,891	112·03
Total	8,610,902	7,574,511	113·68

An inspection of the last column shows that these numbers require to be corrected, not only by an allowance for general incompleteness of the records, but by a special addition to counteract the tendency to omit females. During the first seven years this tendency diminished as registration improved, and the numbers of the two sexes approximated more and more to equality; but even with the most intelligent and careful recording agency, the true ratio between the sexes at birth will never be attained in the records until the opinion of the mass of the people on the relative values of male and female life has undergone a complete alteration. The ratios for the first seven or eight years in the table give a curve apparently asymptotic to a certain line, the ordinate of which would stand for the ratio attainable by the greatest care in registration under the present conditions. Representing the above ratios for the first eight years by the formula, $a + \frac{b}{t}$, where t is counted in years from 1877, we find the ordinate of the asymptote, a, to be 108·57. In the provinces there are, however, two districts in which the numbers born of the two sexes invariably approach much more nearly to equality. One is Garhwál, a Himalayan district inhabited by an unsophisticated people who claim to be *Rájpúts*, but are probably of aboriginal descent, and who have never come under Muhammadan influence in any way, or acquired the custom of paying a heavy dowry with the bride, which is the cause of female infanticide among many of the higher castes. The other is Lalitpur, in the extreme south, where the inhabitants are chiefly *Chamárs* and other low castes, who have never concealed their women or practised infanticide, and amongst many of whom the bridegroom's family pay for the bride. The statistics for these two districts give a series of ratios represented by a curve whose asymptote has an ordinate of 100·00, or which points ultimately to exact equality between the sexes. In like manner, if we select for each year that district in which the recorded birth-rate was highest, and where, therefore, the registration was presumably most complete, we get a curve pointing to an ultimate ratio of 102·78 males to 100 females. If we take the mean of all three results, that for Garhwál and Lalitpur being probably below the true average for the whole population, we get 103·78 males to 100 females. This comes very near the ratio for England, which, I believe, is between 103 and 104, and is almost identical with that deduced from the distribution of the population according to age and sex at the last two censuses of the North-West Provinces—namely, 103·75. It may therefore be adopted as a close approximation to the truth, and it shows that, in regard to the relative numbers of the sexes, human nature is much the same in the East and West, notwithstanding the deceptive appearance presented by unanalyzed statistics, as well as by public gatherings in countries where respectable women seldom venture out of doors.

* Estimated from those registered in municipalities.

The numbers of females in the above table must therefore be all recast so as to give 103·78 males for every 100 females.

This special inaccuracy in the birth tables being corrected, there remains the general inaccuracy due to incompleteness of the register, which is common to both births and deaths, and has been estimated by Dr. Planck, after careful and extended personal inquiry, at 20 per cent. of the total, or one-fourth of the numbers recorded. When both causes of error are allowed for, the total number of births in each year will be as in the second column of the next table. The third column gives the recorded deaths, increased by 25 per cent. to make them represent approximately the true mortality, and the last shows the increase or decrease of population each year, due to these causes. The figures in this column represent very fairly the total gain or loss of population, for the number of emigrants is only three or four thousand annually, and this loss is partly balanced by a return migration, the numbers of which are not known.

Year.	Births.	Deaths.	Increase.
1878	1,639,544	1,902,175	−262,631
1879	1,644,320	2,393,124	−748,804
1880	1,835,850	1,601,544	+234,306
1881	2,327,335	1,753,091	+574,244
1882	2,149,219	1,856,409	+292,810
1883	2,334,062	1,520,371	+813,691
1884	2,493,036	1,944,177	+548,859
1885	2,350,606	1,763,299	+587,307
1886	2,145,476	1,834,516	+310,960
1887	2,216,030	1,977,174	+238,856
Total	21,135,478	18,545,880	+2,589,598

During the year of scarcity, 1878, and that of pestilence, 1879—for the great epidemic of unprecedentedly fatal malarial fever that year surely deserves the name of pestilence—the net loss of population was over a million; but in the next three years this was fully recovered, and in the succeeding years large numbers were added to the population, especially in the healthy year, 1883. Thus the net gain for the ten years, notwithstanding famine and pestilence, was over two millions and a half, an increase almost unprecedented since the first census in 1853, and doubtless the result of an unusually long succession of abundant harvests. Since 1885, however, the increase has grown less and less rapid; and as another scarcity is now nearly due, if any trust may be placed in the average period of the recurrence of droughts in the past, it seems likely that in the next two or three years the increase may be temporarily stopped.

With these figures, and the fixed point given by the census of 1881, it is possible to find the probable number living at the commencement of each year from 1878 to 1888, and also the mean birth- and death-rate for each year of the ten. The census was taken on the night of February 17, 1881, and the total of the people numbered was 44,107,869. In the Census Report it is, however, shown that over a million females between the ages of 5 and 20 must have escaped enumeration; and when allowance is made for them, the probable accurate total comes out 45,232,391. During January and the first seventeen days of February the increase was 118,532; so at the beginning of 1881 the population stood at 45,113,859. From this starting-point the following figures have been worked out:—

Year.	Number living at Commencement.	Year.	Number living at Commencement.
1878	45,890,988	1884	46,794,604
1879	45,628,357	1885	47,343,463
1880	44,879,553	1886	47,930,770
1881	45,113,859	1887	48,241,730
1882	45,688,103	1888	48,480,586
1883	45,980,913		

The mean number living during the ten years was 46,478,714.

The total area of the united provinces is given in the Census Report as 106,104 square miles. The population is thus at the present time about 457 to the square mile, including in the average the Himalayan province of Kumaon, over 12,000 square miles in area, where the average density is less than 90 to the square mile. There is practically no export trade, except in agricultural produce; hence the whole population is supported directly or indirectly by the agriculture of the province; and there is probably no purely agricultural country in the world, except perhaps some parts of China, where so dense a population is maintained.

The birth- and death-rates and rate of increase or decrease each year, calculated on the usual basis of 1000 living, are given in the next table.

Year.	Birth-Rate.	Death-Rate.	Rate of Increase.
1878	35·83	41·57	− 5·74
1879	36·33	52·88	−16·55
1880	40·54	35·37	+ 5·17
1881	51·26	38·61	+12·65
1882	46·89	40·50	+ 6·39
1883	50·32	32·78	+17·54
1884	52·97	41·31	+11·66
1885	49·35	37·02	+12·33
1886	44·72	38·24	+ 6·48
1887	45·82	40·88	+ 4·94
Mean	45·40	39·91	5·49

The birth-rate, even in the worst years of the ten, was as high as in England, while in the best years it was about 50 per cent. higher. The death-rate averaged nearly forty per mille, and therefore, notwithstanding the high birth-rate, the population increased only at the rate of 5·5 per thousand per annum.

A glance at the annexed diagram will render these data more intelligible. Fig. 1 exhibits the movement of the total population from year to year; and the nearly straight line, marked Fig. 2, shows what this movement would have been had it proceeded uniformly at the rate of 5·49 per mille per annum. The curve has been computed by the formula $P = P_0 r_n$, where n is counted from the beginning of 1883, and consequently the ordinate for 1883, P_0, is the geometrical mean of all the ordinates of Fig. 1. The differences of the ordinates of the first two curves are charted in Fig. 3, which therefore exhibits the extent to which the actual population exceeds or falls short of that given by a uniform movement. This is apparently a periodic function of the time; and if so, the period does not differ much from ten years, since the last ordinate is only slightly greater than the first. Figs. 4 and 5 represent the birth- and death-rates respectively. At first sight these appear to have no relation to each other, as concomitant and opposed variations are nearly equal in numbers. The years of lowest death-rate, 1880 and 1883, were, however, followed by the years of highest birth-rate, showing that healthy conditions conduce to fecundity as well as diminished mortality. An exception to this rule is, however, found in 1879, which, following a healthy year, should have had a high birth-rate, but was marked instead by an exceptionally low one. The year 1878, though a dry and very healthy year, was one in which the vitality of the people reached a low ebb, owing to long-continued scarcity, approaching in some places to famine; for, though few or none actually died of starvation, millions were for many months at starvation-point.

The annual rate of increase per thousand, shown in Fig. 6, is probably the best possible measure of the general well-being of the people, combining as it does the effects of abundance or scarcity of food, which influence the birth-rate, with those of health and disease, on which the death-rate depends. Curiously enough, this index of general prosperity or the reverse is much less liable to sudden fluctuations than the birth- or death-rate alone, and yet, like the numbers represented by Fig. 3, it is apparently subject to a periodic oscillation about a mean value. The length of the period is probably something over ten years, since the last year gives a considerably greater result than the first, though it exhibits a downward tendency. It is therefore possible that the rate of increase of a primitive people, living a natural life untrammelled by too much civilization, and multiplying up to the limit of the means of subsistence, may be subject—like the prices of grain, investigated by Mr. E. Chambers and the late Mr. Stanley Jevons, and like many other terrestrial phenomena—to a periodic variation determined by that of the energy received from the sun. Assuming that there is a variation with a period of eleven years, the rates of increase charted in Fig. 6 lead to the formula, $r = 4·576 + 11·725 \sin\left(\frac{2\pi n}{11} + 262\frac{1}{2}°\right)$. This formula gives the smoothly flowing curve of Fig. 6, which coincides, as fairly as may be, with the curve of actual variations. For the minimum epoch the formula gives 1878·73, and for the maximum 1884·23,—dates which fall suggestively near those of the corresponding phases of solar disturbance.

Into this interesting speculation it is impossible at present to enter further, beyond remarking, as was said at the beginning, that the increase of the population during the last ten years was probably above the average, and too rapid to be maintained. The hypothesis that it is subject to a variation in the eleven-year period leads to the result that the mean for a long term of years is only 4·576 per thousand, instead of 5·49. Now, in the Report on the Census of 1881, the Census Officer, Mr. Edmund White, calculated that the population, as reported, increased only 2·33 per thousand per annum between 1853 and 1881; but it is pointed out that this result was vitiated by an over-estimation in 1853, when the individual members of the population were not counted by name, but only the total number of each family was entered in the census forms. In the sixteen years from 1865 to 1881 the rate of increase was 4·48, and as these years included a fair proportion of good and bad, the rate of movement is probably near the truth. It differs only by a small fraction from the mean rate given by the above formula, according to which the population might be expected to double itself in 152 years, notwithstanding the already great pressure on the soil. In the same Census Report, from the distribution of the population according to age, a mean death-rate of 39·5 per mille is arrived at. This agrees sufficiently closely with the rate here found to warrant the conclusion that the corrections applied to the numbers actually registered cannot be far wrong.

Fig. 7 shows the variations of the average rainfall of the province, for which the general mean of the ten years

was almost exactly 38 inches. Neither the birth-rate nor the rate of increase has any distinct relation to the rainfall, but there are very evident indications of such a relation as regards the rate of mortality. The first seven years witnessed great fluctuations in the rainfall, and these were almost exactly parallel in the death-rates, the wettest years being those of greatest mortality. During the last three years, on the other hand, the death-rate increased slightly as rainfall diminished, and *vice versâ*. Amongst the principal causes of death, cholera and small-pox vary enormously in their prevalence from year to year, these diseases being of an epidemic nature; but the variations do not seem to be related in any way to the rainfall. On the contrary, those from endemic malarial fevers, represented by Fig. 8, follow the rainfall variations very closely, and they are the chief factors in the general mortality.

In my former article, the death-rates from various causes were compared with the prevailing meteorological conditions, not year by year, but month by month. If a similar method be adopted with the statistics of the ten years now available, the conclusions arrived at in the former paper are fully borne out as regards all their more important points, only needing, in one or two instances, slight modifications in detail.

The next table gives the total mortality for each month, computed as a rate per mille per annum, and also the rates for certain specified causes of death, which can in most cases be recognized by the recording agency. In computing these, the registered numbers have all been increased by an allowance for omissions similar to that given above.

Month.	Total Mortality.	Fevers.	Cholera.	Small-pox.	Suicide.	Wounds or Accidents.
January ...	32·71	25·64	0·08	1·16	0·032	0·236
February ...	30·85	22·95	0·08	1·65	0·036	0·255
March ...	30·94	22·26	0·31	2·71	0·062	0·276
April ...	38·26	25·46	2·04	4·79	0·087	0·325
May ...	38·40	25·55	2·32	4·75	0·080	0·366
June ...	36·29	24·12	3·11	3·20	0·083	0·508
July ...	31·41	20·88	2·59	1·71	0·078	0·543
August ...	38·67	26·94	3·08	0·65	0·077	0·535
September ...	45·27	34·39	2·19	0·26	0·084	0·532
October ...	58·60	48·77	2·06	0·12	0·076	0·404

Year ...	39·90	29·98	1·58	1·81	0·066	0·374

This table shows how utterly insignificant as causes of death are cholera and small-pox, the two most dreaded diseases, by the side of fevers, which account for three-fourths of the total mortality.

The monthly mean values of the three chief climatic factors for the last ten years may be compared with the preceding figures. They are:—

	Jan.	Feb.	March.	April.	May.	June.	July.	August.	Sept.	Oct.	Nov.	Dec.	Year.
	°	°	°	°	°	°	°	°	°	°	°	°	°
Mean temperature ...	59·4	64·5	75·0	85·7	90·7	91·2	85·0	83·7	83·2	77·8	67·9	60·3 ...	77·0
Range of temperature ...	27·5	27·4	30·0	30·7	27·1	21·3	13·9	13·1	16·0	25·3	30·7	28·9 ...	24·3
	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.
Rainfall	0·87	0·53	0·56	0·22	0·84	4·60	11·91	10·63	6·07	1·38	0·06	0·42 ...	38·09

These are computed on the average of the whole province, exclusive of the higher hill stations.

The relations of the rates of mortality to these climatic causes will be best seen from the curves marked Fig. 9 to Fig. 16. The general death-rate, and that of fever mortality, which follows it closely, have two maxima in October and April or May, and two minima in July and February or March. The secondary maximum in May is a very important feature in the fever curve (Fig. 13), but rises noticeably above the preceding minimum in Fig. 12, which represents the general mortality, owing to the influence of small-pox and, to a small extent, of cholera. The fatal prevalence of fever seems to be altogether uninfluenced by the temperature (represented by Fig. 9), and its variations are almost exactly opposed in phase to those of the rainfall, shown in Fig. 11; but the maxima and minima nearly coincide in time with those of the daily range of temperature (Fig. 10). These statistics therefore confirm the general experience that people are most subject to fever when the nights are chilly and the days hot. If we neglect the secondary maximum in the hot season, Figs. 11 and 13, representing rainfall and fever mortality respectively, will be observed to be almost identical in form, except that the latter is displaced three spaces to the right. This means that malarial fevers are directly dependent on rainfall, in their annual variation as in the variations from year to year; but it takes about three months in Northern India for the malarial conditions brought about by the rainfall (which probably depend on the growth and decay of vegetation) to attain full development. Dr. Meldrum has shown, in several of his annual reports, that in Mauritius the highest fever mortality follows the maximum rainfall at an interval of about two months, and in Northern India a parallel rule seems to hold, except that the interval is slightly longer.

The meteorological conditions predisposing to cholera are evidently heat and moisture, the disease being more prevalent than usual during the whole hot season from April to October, and dying out in the winter. The cholera curve (Fig. 14), which is drawn on a scale four times more open than that for the total mortality, has two maxima in June and August, and a secondary minimum in July. In most years the first maximum falls in April or May, but it has been thrown forward to June in the average for the last ten years by the excessive mortality of last June, when over 50,000 deaths from cholera were registered.

Regarding small-pox (Fig. 15), shown on the same enlarged scale as cholera, all the remarks in my former article hold good. This disease is at a maximum in April and May, and it diminishes rapidly during the rains, until it almost dies out in October and November. The conditions most favourable to its spread seem to be a high wind, and very dry, or perhaps rather very dusty, air; and the number of fatal cases may be almost exactly represented as a direct function of the wind velocity and the dryness of the air. This result is completely in accordance with all that is known about the cause and mode of propagation of the disease.

Fig. 16 gives the annual variation of the deaths by violence, including under this head both suicides and wounds. The curve is a very smoothly flowing one, with a distinct annual minimum at the coldest time of the year, a steady rise through the dry hot season, and relatively high ordinates throughout the rainy season. The scale of the curve is ten times more enlarged than that of the cholera curve, or forty times larger than the scale of total mortality or fever; but though this magnification renders the annual variation visible, it does not reveal any irregularity except a slight increase in September, when, owing to a long "break," or the premature cessation of the rains, the weather sometimes becomes very much hotter than in July or August. This September maximum is more distinct in the suicide ratios than in those of deaths from wounds. It appears, therefore, that these fatalities from crime, instead of disease, are distinctly subject to climatic causes, and the explanation given in my former article, which attributes them to irritability of temper consequent on long-continued heat and moisture, is the best I can put forward.

When the birth statistics are analyzed with reference to the annual period, results equally striking and curious are brought out. The numbers registered, when tabulated month by month, corrected for the causes of error mentioned at the commencement of this article, and thrown into the form of average rates per thousand per annum, give the following table, in which also the monthly ratios, which are for nine years only, have been slightly altered so as to make the annual mean equal to that already found for ten years:—

Month.	Males.	Females.	Total.	Number of Males to 100 Females.
January	22·67	21·92	44·59	103·42
February	22·31	21·53	43·84	103·67
March	20·72	19·95	40·67	103·86
April	20·17	19·30	39·47	104·51
May	18·46	17·64	36·11	104·65
June	18·12	17·30	35·43	104·74
July	20·80	19·70	40·50	105·59
August	25·81	24·72	50·53	104·41
September	28·85	27·86	56·71	103·55
October	28·30	27·41	55·71	103·25
November	25·89	25·15	51·04	102·94
December	25·36	24·88	50·24	101·52
Year	23·12	22·28	45·40	103·77

From the existence of the *Holi* festival among the Hindus, and of similar spring festivals, accompanied with lascivious songs and dances, among many barbarous tribes, as well as from the traces of such festivals still surviving in Europe, and the hints given by classical writers regarding the nature of certain annual religious mysteries performed by the early Greeks and Romans, anthropologists have thought that possibly, during prehistoric times, the human species, like the lower animals in a state of nature, had an annual pairing-time. If any traces of such a condition still survive, we may with some confidence look for them in India, where a large number of the poorer classes are chronically on the verge of starvation, and the different seasons are sufficiently marked in character to affect people differently both in body and in mind. The birth-rates in the above table, represented by Fig. 17 in the diagram, exhibit a most distinct annual variation, smoother and more uniform in character than any of the mortality curves, and with a range equal to nearly 50 per cent. of the mean value. The minimum falls in June and the maximum in September,—dates which point to a maximum of conceptions in December, and a minimum in September. The latter month is near the end of the long and depressing hot season, when malarial influences are rapidly increasing to a maximum, the food-supply of the year is nearly exhausted, and there is the greatest tendency to suicide. The births, as well as the deaths, therefore, show that at the end of the rains the vitality and energy of the people have reached low-water mark.

In December, on the other hand, not only is the salubrity of the country greatly increased, as shown by the rapid diminution of nearly every cause of death, but food is again cheap and abundant. The crops of millet, on which the poorer classes live, are sown in July and reaped in November. During December and the latter half of November they are threshed out, and then is the season for paying the village functionaries and labourers their share of the produce. Consequently food is more abundant at this time of the year than at any other, and as a result of these conditions we find a large number of births the following September and October.

It thus appears that among the poorest of the population there is probably still a more or less distinct annual reproductive season, but instead of being determined by the returning warmth of spring, as must have been the case in prehistoric Europe, it follows the annual return of healthy conditions with abundant food-supply. That the *Holi* festival occurs in spring, instead of in December, is perhaps to be accounted for as a survival from a time when the ancestors of the Hindus lived in a colder climate.

In the last column of the table are given the monthly values of the ratio of males to females at birth. This appears to be subject to a small but distinct annual variation, with a maximum in July, and a minimum in December; but whether this is a remote and obscure physiological effect of the annual march of the seasons, or only a chance arithmetical result, I cannot say.

Allahabad, February 8. S. A. HILL.

ON THE ORBITS OF AEROLITES.[1]

MY studies have led me to the following three propositions:

1. The meteorites which we have in our cabinets and which were seen to fall were originally (as a class, and with a very small number of exceptions), moving about the sun in orbits that had inclinations less than 90°; that is, their motions were direct, not retrograde.

2. The reason why we have only this class of stones in our collections is not one wholly or even mainly dependent on the habits of men; nor on the times when men are out of doors; nor on the places where men live; nor on any other principle of selection acting at or after the arrival of the stones at the ground. Either the stones which are moving in the solar system across the earth's orbit move in general in direct orbits; or else for some reason the stones which move in retrograde orbits do not in general come through the air to the ground in solid form.

3. The perihelion distances of nearly all the orbits in which these stones moved were not less than 0·5 nor more than 1·0, the earth's radius vector being unity.

The first and thirds propositions are limited strictly by their terms to the meteorites from stone-falls actually witnessed, and also represented by specimens in some one or more of existing collections. The investigations that have led to them have been limited to the same stone-falls. This is not because any line of separation is suspected to exist astronomically between the stone-furnishing and detonating meteors, or even between them and the shooting stars, but because, for manifest reasons, any facts established about these stones have a greater value than similar facts about meteors from which no stones have been secured.

About 265 observed falls are represented by specimens in existing collections. The history of these falls I have searched out with no little pains, so far as the material for such history could be found in books accessible to me. Every direct statement and every indirect indication which I have obtained about the paths of these meteors through the air have been carefully considered, and their meaning and value duly estimated. The determination of the path of a stone-furnishing meteor through the air is greatly aided by the fact that we know at once one point of the trajectory, viz.: the point where the stone strikes the ground. To this fact may usually be added another, viz.: that some of the observations are by persons near the place of fall, and hence their statements of direction, so far as we may trust them, have peculiar significance. In individual cases it will be found that not much reliance can be placed upon the asserted direction of the meteor's motion. But when the results are all

[1] "Upon the relation which the former Orbits of those Meteorites that are in our collections, and that were seen to fall, had to the Earth's Orbit" by H. A. Newton. (From the *American Journal of Science*, July 1888.)

collated there is such a general agreement in support of the first and third propositions set forth above that I am very confident that they are true.

The orbit of a meteoroid about the sun is wholly given when we know these three things, the time when it enters the air, the direction of its motion, and the velocity. The velocity cannot be easily measured directly. But the connection between meteors and comets will be assumed as fully proven. The velocity of the meteoroids (neglecting the increase due to the earth's attraction), ought then to be that of the comets, at the same distance from the sun. The greatest cometary velocity at the distance unity is $\sqrt{2}$, the earth's velocity being unity. The smallest velocity for any known comet is that of Encke's comet, which at the earth's mean distance from the sun is 1·244. It seems safe, therefore, to assume that the meteorites we are considering had velocities relative to the sun not greater than 1·414, nor less than 1·244.

The direction of a meteor's motion through the air is to be determined solely by the evidence of observers of the stone-fall. This evidence needs to be carefully collated, especially when statements apparently conflict. A judicial temper of mind must be preserved in estimating the meaning of the statements, lest the evidence be twisted to the support of some preconceived notion. Knowing the danger, I have tried to keep my own mind free from bias.

We need not know the *exact* day, but we must know the time of day of the stone-fall, else the direction through the air cannot be used. This throws out about one-fifth of the total number of falls named above,—there being no statement of the time of day of the fall attainable. There are left 210 different cases available for use. For 94 of these there is no reliable statement of the direction of the motion of the meteor. We know only the day and the hour. Even this, however, is of some value, since we know that the meteor must have been moving downward at the place of fall; that is, from some point of the heavens then above its horizon. For 116 stone-falls the direction of the motion of the meteor is more or less definitely indicated by the statements of observers, or by the statements of those who have inquired into and reported the facts of the falls.

We may then divide the observed stone falls into three groups which will be separately considered: (*a*), 116 falls for which we have statements as to the direction of the path through the air; (*b*), 94 falls of which we know the time of day; (*c*), 50 or more falls of which the history is too scanty to give the time of day.

There is frequent occasion to speak of two points on the celestial sphere for which the English language has no good names. These are the point from which a body is moving, and the point to which a body is moving. These two points are opposed to each other, as north is to south, east to west, zenith to nadir. The words *quit* and *goal* will be used to denote these two points. The *earth's quit* is that point of the ecliptic from which the earth is moving, the *earth's goal* that point to which the earth is moving; the one being about 90° ahead of the sun in the ecliptic, the other 90° behind it. A *meteor's quit* is that point of the heavens from which the meteor is moving; its *goal* that point of the heavens to which it is moving. The motion may be that relative to the earth, in which case the point of the celestial sphere from which it is moving is the meteor's *relative quit*. Thus the relative quit of a meteor when it is entering the air must be above the horizon of the place of entrance, inasmuch as the meteor must be moving downward. If a meteoroid's motion be corrected for the earth's motion the direction of its absolute motion about the sun is obtained, and then the two points of the celestial sphere from which and to which the meteoroid is moving are its *absolute quit* and its *absolute goal*.

The observations have been treated graphically. They do not demand nor do they admit of greater accuracy in methods of discussion than can be used in graphic processes, and these processes have many advantages over numerical computations. A stereographic projection of two hemispheres was prepared and printed, upon which there were three sets of coordinate lines from three sets of poles. The three sets of points were the angles of triquadrantal triangles. Thus the lines were drawn to represent at intervals of 10° the distances and directions from the poles P, P, S, E, and G, Q, (Fig. 1). In the engraved figure these coordinate limes are omitted. The common diameter of the two hemispheres E S E was made to represent the ecliptic, and the sun was placed at the centre or at the edge of one of the hemispheres. The points P would then be the poles of the ecliptic, and if S be the place of the sun the earth's quit will be Q, and the earth's goal G.

To treat any single meteor a large celestial globe was first set for the time and place of the fall. Upon the globe the celestial latitude and longitude of the zenith and of the west-point were then measured. The day of the year gave the sun's longitude. The zenith and west-point could then be marked upon the chart, after which it was easy to draw the circles representing the meridian and the prime vertical. The stereo-graphic projection was peculiarly advantageous in this work as all circles are represented by circles, and angles are conserved in the projection. The effort was then made to mark upon the chart the meteor's relative quit as accurately as the observations permit, or rather to describe an area within which the quit was probably or certainly located

Some of the 116 meteorite quits have been heretofore fairly well determined by other persons, or they can be so determined. This is the case with the meteors of Agram, Weston, Orgeuil, Pultusk, Iowa, Rochester, Estherville, Krahenberg, Khairpur, Vendome, etc. For other cases we are able by comparing the various statements of observers to locate approximately the relative quit. But for a considerable number of the falls we have to be content with the simple statement that the stones came from the north, or from the northeast, or from the south-southeast, or from some other similarly defined direction. When this has been the case I have taken a point 20° above the horizon in the direction indicated, and considering this as the centre of an area of considerable size within which the quit was probably located, have treated the point itself as the meteor's quit.

These observations of direction in some cases will be in error, or will be perverted in reporting, as every one who has tried to reconcile numerous accounts of a meteor has unpleasantly learned. But when the statements have come from persons who saw the stones come down, they are usually of much more value than similar reports about ordinary meteors. In any case when the reports are single they must be taken for what they are worth. I have plotted them as given.

In several notable instances where there are full accounts I have not been able to accept the conclusions heretofore arrived at as to the direction of the meteor's path. . Thus, Dr. Bowditch made the path of the Weston meteor to be from north to south and parallel to the horizon. I make it to have moved from a point N. 40° W., 35° high. The Cold-Bokkeveld meteor was described by Sir Thomas Maclear as moving from the west-north-west. It apparently moved in the opposite direction; that is, from the east-south-east. The l'Aigle meteor was described by M. Biot as moving from the south-south-east, whereas it is well nigh certain that it came from the north-west. In like manner the Stannern meteorite was assumed by von Schreibers to have come from the north-north-west, whereas there are reasons of great weight for believing that it came from the opposite direction. I may add that these and other like changes are not made under any pressure or bias to prove my propositions. In fact three of the four changes just named make the evidence for my conclusions weaker instead of stronger.

In the treatment of the observations several quantities have been neglected as not large enough to be comparable with the probable errors of the observations themselves. Thus the effect of the earth's attraction in changing the direction of motion, or what has been called the *zenithal attraction* of the quit, has been allowed for only in a general way. So the earth's quit and goal are treated as being exactly 90° from the sun; or, in other words, the earth's orbit has been treated as a circle. In like manner the motion of the place of fall due to the earth's rotation on its axis has not been taken account of.

Having located upon the chart the meteor's relative quit we have next to construct its absolute quit. This evidently lies on the great circle joining the relative quit to Q (Fig. 1), which, when the sun is at S is represented on the chart by a straight line through Q, together with its corresponding line through G. When the absolute velocity of the meteroid in its motion about the sun is given, the place on this circle of the absolute quit can be determined by combining by the parallelogram of velocities the motions of the earth and of the meteoroid. The following table is an abstract of a larger one used in this reduction, and is constructed for the limiting velocities 1·414 and 1·244:—

Table showing the Distances from the Earth's Quit to the Absolute Quit of a Meteoroid for Different Distances from the Earth's Quit to the Relative Quit of the Meteoroid.

Distance from Q to relative quit.	Distance from Q to absolute quit. $v = 1{\cdot}414$.	$v = 1{\cdot}244$
30°	9°·3	6°·3
60	22·1	15·8
90	45·0	36·5
120	82·1	75·8
150	129·3	126·3
180	180·0	180·0

In the following constructions the maximum velocity of the meteoroid has been used. When the meteoroid's

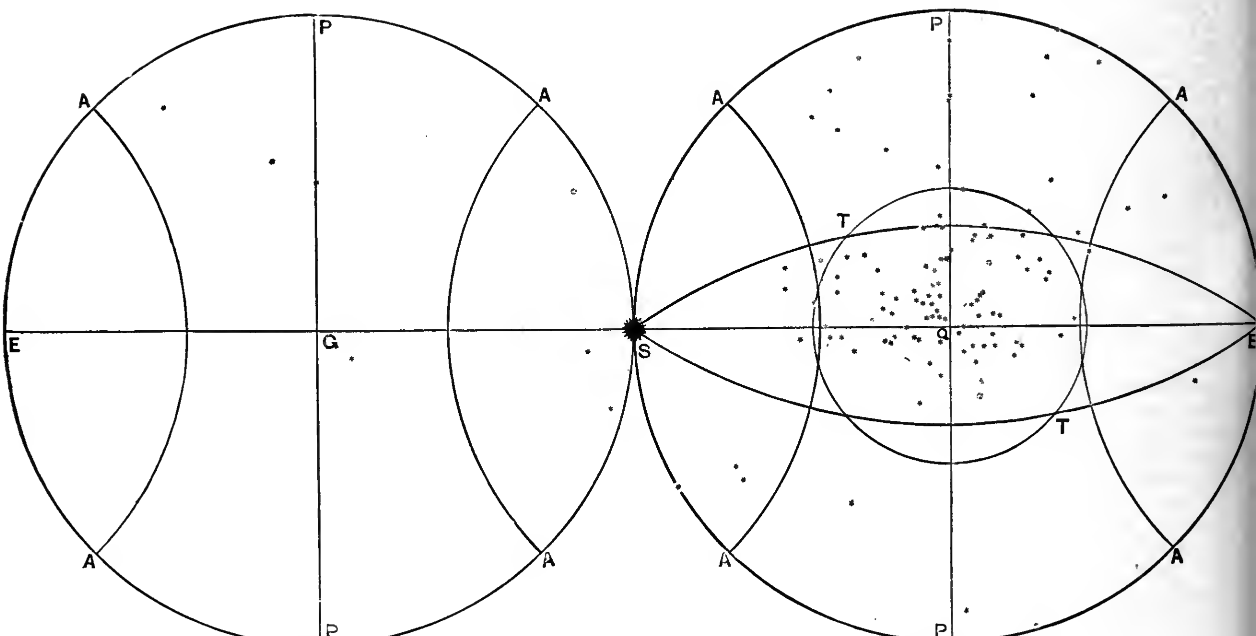

FIG. 1.—Showing the distribution of 116 meteorite quits relatively to the sun's place and to the earth's quit.

relative quit is known as a point the absolute quit is at once constructed. If, however, we have an area within which the relative quit is probably located we may mark off with equal facility points on the boundaries of the area within which the absolute quit is probably located. If the former area is a circle the latter will be an oval. The centre of the circle does not correspond exactly to the centre of the oval, but by applying a correction to the table the centre of the oval absolute quit area can be directly constructed from the centre of the circular relative-quit area.

In Fig. 1 I have given in a single diagram constructed on a stereographic projection, the results for 116 stone-falls. The best determinations which the accounts admit of for the meteor's direction were first made out. Then the centre of the probable quit area in each case was assumed to be the actual quit. When only the quarter of the heavens from which the stones came is stated the centre of probable area was taken 20° above the horizon. Interpreted thus, the stars in Fig. 1 represent the places of the 116 absolute quits relatively to the place of the sun, S, and to that of the earth's quit and goal, Q and G.

Let us denote any one of these quits (or stars), by the letter q. The elements of the orbit in which the corresponding stone was formerly moving can be easily obtained from the projection. The earth's longitude on the day of fall is the longitude of the node. The angle qSQ is the inclination of the orbit to the ecliptic, and its amount is at once read off on the projection. The orbit has been assumed to have been a parabola. Hence, twice the complement of qS was the angular distance of the stone from its perihelion. If $q\text{S} > 90°$, the perihelion had not been reached; if $q\text{S} < 90$, the perihelion, had been passed. The perihelion distance was $\sin^2$QS. If, however, it be assumed that the orbit was a long ellipse of given major axis, the place of the absolute quit, q, moves somewhat nearer to Q along the line qQ, the angle in the plane of the orbit from perihelion was a little more than twice the complement of qS, and the perihelion distance somewhat less than $\sin^2 q$S. But all these quantities are easily computed in terms of the assumed major axis. With a semi-major axis as large as 5 the change in Fig. 1 would not be so considerable as to modify any conclusions we can deduce from the grouping of the stars.

The most noticeable fact revealed by the figure is the clustering of the stars about the point Q. All but seven of the 116 meteor quits are in the Q hemisphere; that is, had orbits whose inclinations were less than 90°. One hundred and nine followed the earth, seven met it. Again the two lines STE are drawn to represent circles inclined 35° to the ecliptic. More than two-thirds of the meteor quits lie between these two lines; hence, over two-thirds of the orbits were inclined less than 35° to the ecliptic, the motion being direct.

It should be said that this clustering of the points near Q is somewhat exaggerated in the figure by the nature of the stereographic projection. The scale of distances near Q differs from that near the circumference. But this does not affect the distribution between the hemispheres.

It has been assumed that certain centres of quit areas were themselves the quits. Can the condensation of the quits near Q have been caused in any way by this assumption? Or, is it possible that general errors of observation, or inaccuracy of reporting, could have been the cause? To answer this question let us suppose that there had existed a law that led to condensation of the relative quits in any manner whatever. The effect of the errors of observing or reporting, and also the effect of the assumption above stated, would be toward scattering these relative quits over the heavens more equably, and thus masking the law. Then when the relative quits thus unduly scattered are reduced to absolute quits there might be as a result a tendency towards condensation near Q. If, however, we draw the circle TT, enclosing those absolute quits whose relative quits are in the hemisphere next Q, the general tendency of the errors in question would be towards equalizing the number of absolute quits within to those without the circle TT. Now, the number of stars is nearly twice as great within

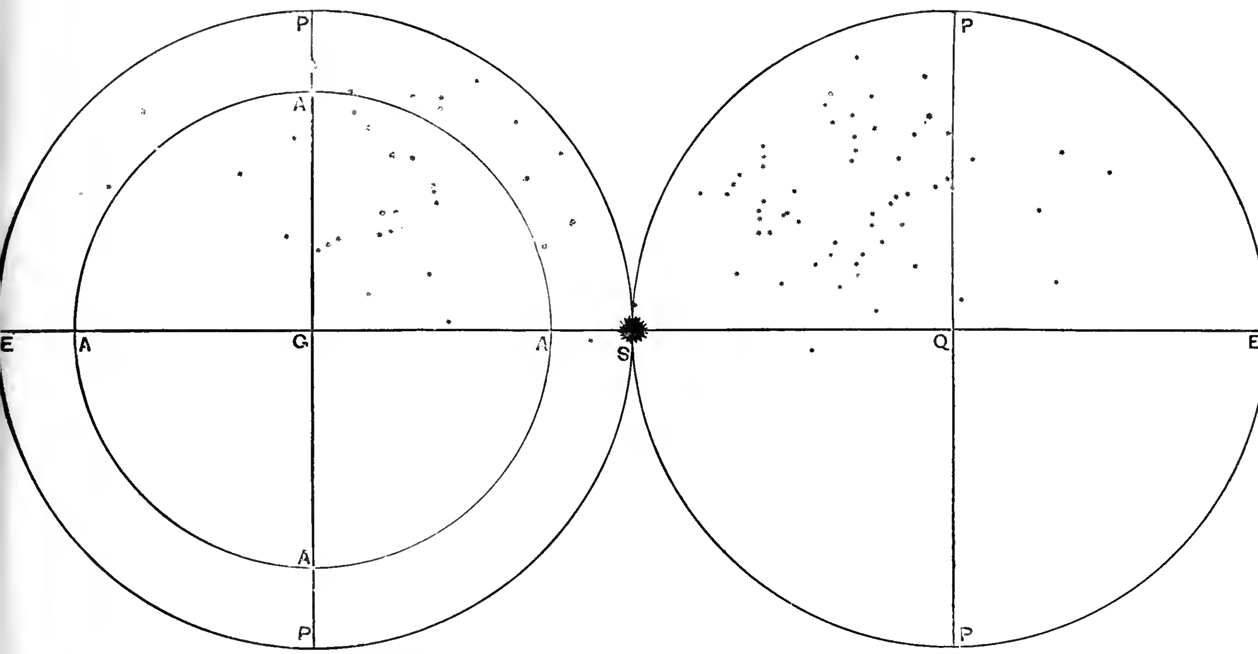

FIG. 2.—Showing relatively to the sun's place, the zeniths for the time and place of 94 stone-falls.

as without the circle. The condensation about Q, shown in Fig. 1, exists therefore in spite of, and not in consequence of, these errors. With a good deal of confidence do I conclude that these 116 meteors were, as a class and with probably a very few exceptions, before coming into the air following the earth in its orbit about the sun.

Another fact of great interest is also shown by the grouping of the points in Fig. 1. In general these stones did not go in their orbits very near to the sun. Assuming that the orbits were parabolas we have for all the stones whose perihelion distances were less than one-half, $\sin^2 qS < \frac{1}{2}$. If there be drawn circles, AA, AA, 45° from S and from E, then will all the stones whose absolute quits were in the central zone, A P P A A A which is bounded by the circles A A, have perihelion distances greater than one-half and less than unity. Of these there are 103 out of a total 116. If the same orbits are assumed to have had semi-major axes equal to 5, then the circles A A would have to be drawn a fraction of one degree farther from S and from E to serve as the limiting curve to orbits whose perihelion distances exceed one-half.

It appears from Fig. 1 that these 116 stones were, with a few exceptions, following the earth in their orbit about the sun. This could happen from either one or more of three possible causes:

Firstly, that nearly all the stones in the solar system are moving in direct orbits, very few in retrograde orbits;—

Or, secondly, that stones moving in retrograde orbits for some reason, as for example their great relative velocity, may not have been able to pass through the air and to reach the ground in solid form;—

Or, thirdly, that stones moving in such retrograde orbits, and coming through the air, may be falling while men sleep, or for some like reason may fail to be found. In other words, the effective cause may work above the air, in the air, or below the air.

Let us assume, as an hypothesis, that neither of the first two are the true causes. In that case we should have the stones moving in every direction as they cross the earth's orbit. There should be about as many orbits having retrograde motions as direct motions. Hence the absolute quits of all stones coming into and hence, by hypothesis, coming through the air, should be symmetrically distributed in their longitudes relative to the sun. At least there should be as many absolute quits in the G-hemisphere as in the Q hemisphere (Fig. 1). Take account now of the earth's motion and locate the relative quits. All these stones whose absolute quits lie outside of the circle T T will have their relative quits in the G-hemisphere. Upon the hypothesis of parabolic orbits and of an equable distribution of the absolute quits over the celestial sphere the number of relative quits in the G-hemisphere should be to those in the Q-hemisphere as $1 + \cos \frac{\pi}{4} : 1 - \cos \frac{\pi}{4}$, or as 17:3. The relative quits should then be *very much* more numerous in the G-hemisphere than in the Q-hemisphere.

Furthermore, suppose that the heavens visible at a given time and place, are divided by a vertical circle into two halves; and suppose that this vertical circle is at right angles to the plane containing the zenith and the earth's quit and goal. That half of the visible heavens that lies towards the earth's goal may be called the goal-half, the other half may be called the quit-half of the visible heavens. In any given period there should evidently be, under the several hypotheses stated, many more stones coming into the air and reaching the ground directed from the goal-half than there should be directed from the quit-half of the visible heavens. Still further, since this proposition applies to any epoch whatever, we may apply it to 116 periods covering the times of the 116 stone-falls, that is, to the 116 stone-falls themselves Many more of these should (under the hypotheses stated) have come from the goal-half than from the quit-half of the visible heavens.

If, then, the relative quit of each of these 116 stones is supposed to be carried around in azimuth 180°, the altitude being unchanged, the 116 distances from each new place of the quit to the earth's quit for the epoch of the fall should, in the average, be decidedly less than the corresponding 116 distances from the actual relative quits to the earth's quit. This should hold true (under the hypotheses stated) no matter what causes below the air may have occasioned the selection of the 116 epochs. The fact that more persons are abroad in the evening hours from 6h. to 10h. p.m., than in the corresponding morning hours, 2h. to 6h. a.m., may well cause that more stones should be secured in the evening than in the morning hours. In the evening hours the earth's quit is above the horizon; in the morning hours the earth's goal. It might easily be that we should for this reason get more stones of direct than of retrograde motions. But the above criterion is entirely independent of any such principle of selection of the epochs. A change of the azimuth of the quits through 180° should cause a larger number of them (under the hypotheses stated) to approach the earth's quit than to recede from it.

I have marked off upon the working sheets the position 180° in azimuth from each of 115 relative quits, the altitude being unchanged, and measured the several distances from the earth's quit. (One fall, Nedagolla, was unavailable). The following is the result. In 44 cases the meteor's quit by the change approaches the earth's quit: in 70 cases it approaches the earth's goal; in one it remains unchanged. That is, instead of a very large majority of the quits moving towards the earth's quit we have nearly two-thirds of them moving the other way. In the reversed position, moreover, we should have had 38 absolute quits in the G-hemisphere instead of 7. These numbers show very decidedly that the hypotheses made above are not true. The principle of selection is not *entirely* below the air, and the numbers testify so markedly against that hypothesis that I feel warranted in adding that the cause is *mainly* either above the air, or in the air.

Between the first and second causes named the materials used for the present discussion do not furnish a *positive* critical test. But if, as I believe, the Stannern stone came from the south, we have at least one instance of stones coming into the air with a velocity of nearly, or quite, 45 miles a second and reaching the ground in solid form. About twenty-five of the quits in Fig 1 imply velocities of not less than 25 miles a second on entering the air. Large velocities do not seem to be entirely fatal to the integrity of the meteorites. I believe that the first cause was the dominant one rather than the second, yet for a crucial test of the two causes, if one can be found, we must look to a class of facts other than those we have been considering.

We are now in position to consider the other ninety-four stone-falls. In Fig. 2, the construction of which is similar to that of Fig. 1, the stars mark the zenith points for each time and place of the ninety-four falls. A grouping is at once noticeable. They are nearly all in the northern hemisphere, since the observing peoples live there. Those stars in the hemisphere of which S is the pole, that is between the two lines P P and P P, are evidently daylight stone falls, since S is above the horizon for each case. These constitute about seven-eighths of the whole number. The reason for this predominance is manifest. In the night men see the fireball or the train, whereas in the day the first intimation of the stone fall is usually the hearing of the detonation two or three minutes after the fireball has disappeared. Hence, daylight stone-falls are those whose directions are less likely to be observed, and these ninety-four falls are the ones of which the directions are unknown.

It will also be seen that there are nearly twice as many in the Q-hemisphere as in the G-hemisphere; that is, there are nearly twice as many that fell when the earth's quit was above the horizon as there were when the earth's goal was above the horizon. In general, the former were afternoon stone-falls, the latter forenoon stone-falls. Now the habits of the urban population have not much to do with these daylight meteors, for the fireballs were not seen. The accounts come from the country, where the stones in general have fallen, and about as m ny people are there abroad in the forenoon as in the afternoon. If stones came to the ground as often from retrograde as from direct orbits we ought apparently to have had very many more zeniths in the G-hemisphere than in the Q-hemisphere. The contrary being the fact of experience we may reasonably say that the ninety-four stone-falls, about which we know comparatively little, seem decidedly to follow the same laws as the 116 falls about which we know so much more.

This conclusion is greatly strengthened if we take account of the effect of the earth's attraction in carrying the meteor's quit toward the zenith. Any stone must be moving downward when it enters the air. But the earth's attraction must change the direction of its motion during the approach to the earth. Hence the region of the heavens from which a stone can approach the earth is not bounded by the actual horizon, but by a curve which may be treated as a depressed horizon. This depression of the horizon is far greater toward the quit than toward the the goal side of the horizon. The maximum depression for a stone moving in a parabolic orbit is about 17°. It hence follows that when the zenith is more than 73° and less than 90° from G, both the points G and Q are above the depressed horizon, and therefore that the 14 falls whose zeniths are between these limits, that is, are between the circles A A and P E P S, Fig. 2, should be left out of the count. The corresponding region on the Q-hemisphere is less than one degree in breadth, and contains one zenith point. We have left only 20 falls when the earth's goal alone was above the depressed horizon to be compared with 59 falls when the earth's quit alone was above the depressed horizon.

Of the 50 observed falls constituting the third group, of which the hour of fall is not stated, very few particulars other than the fact of fall are known. Although we are left without the power of saying that they indicate the same law as the other 210 falls, we find at the same time no reason to suspect the contrary. It is not unreasonable to assume that the well-observed stone-falls are good representatives of the whole group, and to affirm the three propositions with which I set out as true, in general, not only for the 210 stone-falls of the first two groups, but for the whole 260 stone-falls which are represented by stones in our cabinets, and in which the stones were seen or known to fall.

It also seems a natural and proper corollary to these propositions (unless it shall appear that stones meeting the earth are destroyed in the air), that the larger meteorites moving in our solar system are allied much more closely with the group of comets of short period than with the comets whose orbits are nearly parabolic. All the known comets of shorter periods than 33 years move about the sun in direct orbits that have moderate inclinations to the Ecliptic. On the contrary, of the nearly parabolic cometic orbits that are known only a small proportion of the whole number have small inclinations with direct motion.

It also follows that in future reductions of these stone-fall observations it will be better to assume that the velocity of the stone in its orbit was not that velocity which corresponds to a parabolic orbit, but that which corresponds to the mean orbit of the comets of short period. The largeness of the perihelion distances has an evident bearing also upon the idea that these stones form the fuel of the sun.

The presentation of the argument here made has been incomplete in that the details of the investigation of individual stone-falls have been entirely omitted. Some of the determinations of the paths are, I think, as complete as I can hope to make them. But others must be regarded as provisional, since I hope to secure respecting them additional data. I hope at some future time to give a complete discussion of all these observed stone-falls. In the past I have been greatly indebted to friends for aid in collecting accounts of the falls, and I heartily thank them therefore. I shall be very grateful also in the future for unpublished observations of the stone-falls, as well as for observations that have been so published as not to be likely to have attracted attention. I bespeak the kindly aid of any who have made or have collected such observations.

NOTES.

At the time of the Paris Exhibition in 1889, several scientific congresses will assemble in the French capital—congresses of zoology, anthropology, physiology, electricity, dermatology, hygiene. The *Revue Scientifique* expresses a hope that the great congress of electricity in 1881 may be taken as a model for all these assemblies; that attempts will be made, as far as possible, to establish uniformity in scientific nomenclature; and that men of science in other countries will not allow themselves to be deterred by international jealousies from being adequately represented at meetings whose proceedings will relate to matters of universal interest.

At the next meeting of the British Association there will be a discussion in Section D on the vexed question of the formation of coral reefs. The discussion will be opened by Dr. Sydney J. Hickson.

On Tuesday evening Mr. W. H. Smith, speaking of the measures with which it would be impossible to deal during the present Session, announced that the Government had decided to drop the Technical Instruction Bill. He deeply regretted that this was necessary, "but perhaps," he added, "there may not be much loss of time, as the Royal Commission on Elementary Education will report shortly on the whole question, and it will be interesting and convenient to the House to have that report before it before attempting to legislate on the subject."

A Conference of the Executive Committee of the National Association for the Promotion of Technical Education and representatives of branches and co-operating associations was held last Saturday afternoon at the Society of Arts. Afterwards the first annual meeting of the Association was held. Lord Hartington presided, and delivered an able and interesting speech, showing how the establishment of a proper system of technical instruction has been rendered absolutely necessary by the conditions of modern industrial development.

The anniversary meeting of the Sanitary Institute of Great Britain will be held to-day at 3 p.m. The chair will be taken by Mr. Edwin Chadwick, C.B., who will present the medals and certificates awarded to the exhibitors at the exhibition held at Bolton. Dr. B. W. Richardson, F.R.S., will deliver an address, entitled, "The Storage of Life as a Sanitary Study."

On Thursday, the 5th inst., Prof. Stokes distributed the prizes to the students at the Medical School, St. Thomas's Hospital. In addressing the students he said that he need not remind them that diligence was the great road to success, and urged that it was a duty to work for our fellow-creatures as well as ourselves. He thought that the two noblest professions were those, one of which assisted in the rectification of man's character and the other in alleviating the results of disease. In the exercise of the medical profession our best feelings were, he thought, called forth. The best foundation was a general liberal education, and although those branches of science which bear directly on medicine might be separated from their practical application, they were in themselves most interesting, and, when studied for their own sakes, were excellent mental training. He was glad to hear from Dr. Ord that St. Thomas's students were successful in athletics, as the cups exhibited testified. In the necessarily sedentary life of a medical student exercise and relaxation should not be neglected, and students did well to study the use of their muscles in athletic pursuits. Sir John Simon, on behalf of the Governors of the Hospital, thanked Prof. Stokes for distributing the prizes, and referred to the high position attained by Prof. Stokes, who, as President of the Royal Society, and representative in Parliament of the University of Sir Isaac Newton, might be said to have gained the best possible prize, but hinted that the happiness of life consisted in its endeavours rather than in its prizes. He concluded by alluding to the retirement of Dr. Ord, whose services as Dean of the Medical School during the past twelve years had been, he felt sure, much appreciated by the Governors of the Hospital, by the medical and surgical staff, and by the students.

The French Minister of Public Instruction has authorized the following scientific missions:—M. Georges Martin is entrusted with a mission to Sweden and Norway, to study the different educational questions; M. Henry Meyners d'Estrey is sent to explore the mountainous districts of Scandinavia, and to study certain questions connected with ethnography and anthropology; M. Gaston Angelvy, civil engineer, goes to explore the tract of country between Lake Nyassa and the coast of the Indian Ocean, and to visit more particularly the basin of the river Royaurva.

The Musée Guimet in Paris, which contains specimens of a great number of objects used in religious ceremonies, was nominally opened some days ago. It will not, however, be opened to the public for several months.

THE meeting which will shortly be held in Paris for the study of tuberculosis, under Prof. Chauveau's presidency, promises to be very interesting and successful.

THE International Congress of "Americanists" will hold its seventh session in Berlin from October 2 to 5 next. The organizing committee has just issued the programme. The first day will be devoted to questions relating to the discovery of the New World, to the history of America before the time of Columbus, and to American geology; the second to archæology; the third to anthropology and ethnography; the fourth to philology and palæography.

IT is proposed that an exhibition, to be called the "Three Americas Permanant Exhibition," shall be established at Washington in 1892 as a memorial of the discovery of America by Columbus. Both Houses of Congress have expressed approval of the scheme. While the subject was being considered by the House Committee on Commerce, Major J. W. Powell, director of the U.S. Geological Survey, pointed out, in an interesting address to the Committee, the benefits that archæologists would be likely to derive from such an exhibition, and the importance of securing without delay the necessary materials.

WE have received the volume containing a report of the Proceedings of the thirty-sixth meeting of the American Association for the Advancement of Science, held at New York in August, 1887. Among the more interesting contents of the volume is the address of Dr. Daniel G. Brinton, vice-President of the Section for anthropology. In this address Dr. Brinton presents a comprehensive review of the data for the study of the prehistoric chronology of America. Speaking of physical characteristics, he says that although the anatomy and physiology of the various American tribes present great diversity they also display a really remarkable fixedness of type. No observer well acquainted with this type could err, he thinks, in taking it for another. "Darwin says that the Fuegians so closely resemble the Botocudos [of Brazil] that they seemed members of the same tribe. I have seen Arawacks from Guiana who in the north-west would have passed for Sioux." According to Prof. J. Kollmann, the results of whose researches on this subject are accepted by Dr. Brinton, the essential physical identity of the American race is as extended in time as in space. Prof. Kollmann has analyzed the cranioscopic formulas of the most ancient American skulls, those from the alleged tertiary deposits of the Pampas, that obtained from Rock Bluff, Illinois, the celebrated Calaveras skull from California, and one from Pontemelo in Buenos Ayres of geologic antiquity. The conclusion at which he arrives is that the earliest Americans—those who were contemporaries of the fossil horse and other long since extinct quadrupeds—possessed the same racial character as the natives of the present day, with similar skulls and a like physiognomy.

ON Monday the atmosphere in the Channel became so rarefied that objects could be seen with extraordinary distinctness at a distance of between 30 and 40 miles from Dover and Folkestone. The *Times* says that the lighthouse at Cape Grisnez, Calais, and the dome of the Cathedral, and Napoleon's Column at Boulogne could be distinctly seen with the naked eye, and every prominent object could be picked out along the French coast. The distance from Dover to Boulogne as the crow flies is 28 miles, and the column is about 2 miles further inland.

THE following telegram from Valparaiso was lately received at Buenos Ayres:—"A rather severe earthquake shock was experienced in Santiago on Sunday, May 13, at 11.30 a.m., and considerable alarm prevailed in consequence of May 13 being the anniversary of the great earthquake in 1647, which laid a large portion of the city in ruins, and which was the origin of the procession of the Señor de Mayo. A severe but short vertical shock occurred here on Tuesday, the 15th, at 8.5 p.m. A strong earthquake shock was felt at Yumbel on the 10th, at 9.15 p.m. A smart earthquake shock, preceded by a long subterranean noise, was experienced in Santiago on Wednesday, the 16th, at 4.55 a.m. The shock was also felt here, but slightly." At Buenos Ayres several earthquake shocks were experienced on the night of Monday, June 4. According to the *Buenos Ayres Standard*, a slight shock was felt at 12.18. Three seconds afterwards a very strong shock occurred, and the oscillation was slow and pronounced. The walls of houses and all movable articles were shaken, and a third shock, which seemed to be nothing more than the subsidence of the second, occurred two seconds afterwards. No serious accident followed the occurrence. Several families, however, were so startled that they rushed out of their houses and sought refuge in the open square. The shocks were felt with more or less intensity all over the province of Buenos Ayres and in Montevideo. As felt in Montevideo the shock passed from south-south-west to north-north-east.

AT the meeting of the French Meteorological Society on June 5, M. Angot communicated a paper on the climate of St. Martin-de-Hinx (Landes) based on observations made since 1864, in which he has determined the diurnal variations of each element. He also announced that as soon as funds were obtained he intended to publish *in extenso* several long series of observations. At several of the places mentioned, including Paris, Marseilles, &c., the observations date from far into the last century. M. L. Teisserenc de Bort communicated a note relative to two earthquakes which occurred at 8 p.m. on the 4th, and at 5 p.m. on May 14 last, in the department of Puy-de-Dôme. M. Moureaux remarked that the magnetograms at Parc-St.-Maur showed no special disturbances at those times. M. Renou paid a tribute to the memory of M. Hervé-Mangon, to whose exertions the separation of the meteorological from the astronomical service was due. This memoir will be printed in the Bulletin of the Society.

A NEW base and its series of salts, belonging to the remarkable group known as "platinum bases," have been obtained by Dr. Heinrich Alexander, of Königsberg. The base itself has the composition $Pt(OH)_2 . 4NH_3O$, and may be considered as the hydroxylamine-platinum compound corresponding to the free base of the well-known green salt of Magnus, $Pt(OH)_2 . 4NH_3$. The chloride of the series was prepared some little time ago by Lossen, but can be most readily obtained, according to Alexander, by mixing a 10 per cent. solution of potassium platinous chloride with hydrochloride of hydroxylamine and an alkaline carbonate. On standing, the deep red liquid becomes decolourized, and the reaction is completed when a yellowish precipitate commences to settle; on the addition of more alkali the new base is immediately and quantitatively precipitated. The precipitate is then dissolved in the calculated quantity of cold dilute hydrochloric acid, and on passing a gentle stream of hydrochloric acid gas through the solution, or on the addition of absolute alcohol, fine colourless needles of the chloride $PtCl_2 . 4NH_3O$ are deposited. These needles are very soluble in water, but, like many other chlorides, are insoluble in concentrated hydrochloric acid. The free base is at once precipitated from this salt on the addition of stronger bases, such as potash and soda, or even ammonia. It is perfectly stable in the air and is extremely insoluble in water and alcohol; it behaves exactly like a true metallic hydroxide, dissolving in acids with formation of the corresponding salts. The sulphate $PtSO_4 . 4NH_3O$, which is best obtained by treating the base with the calculated quantity of sulphuric acid upon a water bath, crystallizes well in short, heavy prisms, difficultly soluble in cold but better in hot water, the crystals deposited from which contain a molecule of water of crystallization. When heated above 100° C. it violently decomposes with detonation. In a similar manner the phosphate and oxalate of the series were obtained pure and analyzed. The former separates out in microscopic crystals while the latter is deposited in beautiful stellar aggregates of long needles. During the course of the work, two interesting isomeric salts were obtained. When the base is treated with excess of warm hydrochloric acid and the solution allowed to cool, yellow needles of a chloride of the composition $PtCl_2 . 2NH_3O$ fall out. If however potassium platinous chloride be added to dilute solutions of the first chloride, $PtCl_2 . 4NH_3O$, beautiful violet needles of an isomeric salt, $PtCl_2 . 4NH_3O + PtCl_2$, separate out. The two substances are quite distinct, though possessing the same empirical formula, reminding one of the remarkable isomerism so frequently met with among the compounds of carbon.

UNDER the heading of "Psychology" the *American Naturalist* for May has a curious paragraph on "The Monkey as a Scientific Investigator." In the interesting little "Zoo" connected with the National Museum at Washington, there is a fine male grivet monkey (*Cercopithecus erythræa*), who shares a large cage with four opossums. To human beings he shows himself anything but amiable, but "he takes kindly to his strange companions, and they have been the best friends from the first." The attention of the attendant was lately drawn to the cage by the excitement of a crowd in front of it, and on going to ascertain the cause he was surprised to see the monkey seated in the middle of the cage, with one of the opossums lying quietly on her back on his lap, and her head under his arm. "The monkey had just discovered the marsupial pouch of the opossum, and was diligently investigating it. Had he not been a close observer it certainly would have remained unseen, for it was so tightly closed as to be perfectly invisible in its normal condition. The monkey carefully lifted the outer wall of the pouch, and peered into the cavity. Then he reached in with his hand, felt about for a moment, and to the astonishment of everybody took out a tiny young opossum, about 2 inches long, hairless, blind, and very helpless, but alive and kicking. Jock held it up to the light, where he could get a good view of it, scrutinized it with the air of a *savant*, and presently returned it to the pouch, very carefully. After replacing it he looked into the pouch again, and presently drew out another for examination, which he looked at with solemn interest, smelt it, and then carefully put it back. It was thus it became known to the attendants that the old female opossum had the young ones, which had previously been looked for in vain."

SOME time ago an English resident at Canton, Mr. Pitman, bought a curious monstrosity—a sow with six legs. The front part of the body is simple, that is, the animal has one head, one thorax, and two front legs. Behind, all the organs are double. M. Bézaure, the French Consul at Canton, persuaded Mr. Pitman to let him have this strange creature for the Paris Museum of Natural History, where it may now be seen. It is white, with great black spots, and appears to be in perfect health. An account of it, by M. Charles Brongniart, of the Museum of Natural History, appears in the current number of *La Nature*. The separation of the two trunks seems to begin after the dorsal vertebræ; but the animal is so fat that this cannot be precisely determined.

MANY women who are anxious to obtain a University training cannot afford to pay the fees required for residence at one of the colleges or halls in connection with the old Universities. For their benefit Aberdare Hall, Cardiff, was founded; and we are glad to learn that the institution has made steady progress since it was opened in 1885. This year the number of students has doubled. At University College, Cardiff, the students at Aberdare Hall are taught on the same footing as the men students. They generally work for London University degrees, but when they wish to prepare for other examinations the necessary help is gladly given.

THE Irish Exhibition in London has published a useful "Handy-book of Reference for Irishwomen." It is edited by Miss Helen Blackburn, and Mrs. Power Lalor contributes a preface. The volume presents full and accurate information as to women's work in Ireland, and as to the schools and classes in which they may obtain scientific and technical training.

THE annual report of the Geological and Natural History Survey of Canada for 1886 (vol. ii. new series) has been issued. It embodies the results of some of the work of preceding years, and not all of the work of the year for which it is dated. The volume consists of thirteen parts, separately paged and lettered, and relating to various portions of the Dominion from Nova Scotia to British Columbia, and northward to the Arctic Ocean. The parts were issued separately with accompanying maps and illustrations in pamphlet form, as they were received from the printers.

THE new number of the *Mineralogical Magazine* contains, besides abstracts and a full index to vol. vii., the following papers:—On the development of a lamellar structure in quartz-crystals by mechanical means, by Prof. John W. Judd, F.R.S.; on the polysynthetic structure of some porphyritic quartz-crystals in a quartz-felsite, by Major-General C. A. McMahon; on kaolinite, by Alan Dick; note on the occurrence of celestite containing nearly 14 per cent. of free sulphur, by H. J. Johnston-Lavis; notes on hornblende as a rock-forming mineral, by Alfred Harker.

M. VAYNIÈRE has brought out the second of the four parts of his Atlas of invertebrate animals.

IN a circular issued by Mr. Edward S. Holden, director of the Lick Observatory, it is stated that the Observatory buildings will be open to visitors during office hours every day in the year. An hour or so, he points out, can be profitably occupied in viewing the various instruments, and the rest of the stay can be well spent in walks to the various reservoirs, from which magnificent views of the surrounding country can be had. With regard to the admission of visitors at night, Mr. Holden says that, for the present, visitors will be received at the Observatory to look through the great telescope every Saturday night between the hours of 7 and 10, and at these times only. Whenever the work of the Observatory will allow, other telescopes will also be put at the disposition of visitors on Saturdays between the same hours. Mr. Holden hopes that, by setting apart these times for visitors (which allow freer access to the Lick Observatory than is allowed to any other Observatory in the world) all interested may be able to arrange their visits in conformity to them; and that the remaining hours of the week will be kept entirely uninterrupted, in order that the astronomers may do the work upon which the reputation of the Observatory entirely depends.

FROM a report signed by Mr. Edward S. Holden we learn that the trustees of the Lick Observatory, acting on his advice, have provided a photographic attachment to the 36-inch telescope, which will enable this to be used as a gigantic camera for photography. It cannot be used to make maps according to the scheme of the Paris Congress, since that scheme requires a focal length of 13 feet, while that at the Lick Observatory will be 47. But a vast deal of work may be done in connection with applications to astronomy other than the construction of the chart. In the photography of the moon, of the planets, of nebulæ, and comets the Lick telescope will have some important advantages. "But," says Mr. Holden, "it is in the photography of stars—of double and binary stars, of all the fainter stars, of all star clusters — that the Lick photographic telescope will find its chief application and demonstrate its immense superiority. One of the first works to be done is to photograph the vicinity of all the brighter stars, for the discovery of fainter companions, and for the permanent record of their surroundings. A certain number of stars will be selected and photographed at regular intervals throughout the year. Measures made upon these plates will give the data by which the distances of these stars from the earth can be determined. Similar measures upon photographs of star clusters may serve to give us a clue to the laws which govern the internal structure of these wonderful objects. A continuous series of photographs of the brighter parts of one of the brighter comets will certainly throw a flood of much needed light upon the process of their development."

THE additions to the Zoological Society's Gardens during the past week include a White-thighed Colobus (*Colobus vellerosus* ♂), a Campbell's Monkey (*Cercopithecus campbelli* ♀), a White-Collared Mangabey (*Cercocebus collarii*), a Bosman's Potto (*Perodicticus potto*), a Marabou Stork (*Leptoptilus crumeniferus*), a Black Sternothere (*Sternothærus niger*) from West Africa, presented by Mr. H. H. Johnston, F.Z.S. ; two Black-Bellied Sand Grouse (*Pterocles arenarius*) from North Africa, presented by Sir Kirby Green, K.C.M.G. ; an Eyed Lizard (*Licerta ocellata*), European, presented by Mr. J. Hopson ; a Patas Monkey (*Cercopithecus patas* ♀), two West African Love Birds (*Agapornis pullaria*) from West Africa, a Cormorant (*Phalacrocorax carbo*), British, three Scarlet Ibises (*Eudocimus ruber*) from South America, five Common Chameleons (*Chamæleon vulgaris*) from North Africa, deposited ; a Chipping Squirrel (*Tamias striatus*) from North America, five Lesser Pintailed Sand Grouse (*Ptero les exustus* 1 ♂, 3 ♀) from Abyssinia, two Modest Grass Finches (*Amadina modesta*) from Australia, purchased ; a Moor Monkey (*Semnopithecus maurus* ♂) from Java, received in exchange ; a Spotted Tinamon (*Nothura maculosa*), two Cambayan Turtle Doves (*Turtur senegalensis*), three Chiloe Widgeon (*Mareca chiloensis*), three Slender Ducks (*Anas gibberifrons*), two Australian Wild Ducks (*Anas superciliosa*), three Mandarin Ducks (*Æx galericulata*), eleven Chilian Pintails (*Dafila spinicauda*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE MARKINGS ON MARS.—M. Perrotin, in a more recent communication to the Paris Academy of Sciences, states that the district of *Libya*, the disappearance of which he had recorded a week or two earlier (NATURE, vol. xxxviii. p. 185), has undergone a further change, the "sea" which had so recently covered it having retreated again for the most part, so that the present appearance of the district is intermediate between that which it recently presented and that under which it was seen in 1886. Of the canals M. Perrotin has noticed four, three of which are double, which, starting from the "seas" of the southern hemisphere near the equator, and following a nearly meridional course, extend right up to the north polar ice cap, being traceable across the "seas" which immediately surround the latter. No other observer as yet seems to have traced these canals for such a distance, and across "seas" as well as continents. This observation renders their true character more puzzling than ever, and seems effectually to dispose both of M. Fizeau's just published theory, which explains them by the analogy of the rifts in terrestrial glaciers, Mars being assumed to be in a glacial condition, and of that of Mr. Proctor, who ascribes them to the varying appearances of the Martial rivers when clearly seen or partly veiled by local mists. More detailed observations of these strange markings are needed, and it is to be much desired that as many as possible of actual drawings made at the telescope should be published. It is possible that the comparison of sketches made with different observers and with different apertures, would throw much light on the subject ; if, for instance, the appearances were partly optical and due to some effect of diffraction, it would soon become apparent.

COMET 1888*a*, SAWERTHAL.—The remarkable change in brightness which this object displayed about May 20 (NATURE, vol. xxxviii. p. 114) seems to have been well observed, and there is a general agreement that the increase in brightness amounted to 2½ or 3 magnitudes. At Dorpat Herr Blumbach estimated the comet as 9–10 on May 19, and as 7–8 on May 22. Dr. Franz, at Konigsberg, considered the increase as amounting to 3½ magnitudes, estimating the brightness as 5·8 on May 21, whilst Dr. Kammermann, at Geneva, on May 25, reckoned the comet as between the 5th and 6th mags., and the increase as having been between 2 and 3. Father Fenyi, of the Kalocsa Observatory, finds the change of magnitude about the same, but estimates the absolute brightness differently ; the recorded magnitudes being: May 20, 9·3 ; May 21, 7·8 ; May 22, 6·8 ; and May 23, 6·8. Father Fenyi also supplies (*Astr. Nach.*, No. 2844) a series of sketches of the comet, showing the changes of shape which have accompanied the changes of brightness, and especially the development about May 28 of a sort of wing on either side of the head. These wings appear, however, to have been seen earlier at other observatories, thus Herr Kortazzi, at Nicolaiew, observed them on May 24, and Herr Wutschichowski gives a beautiful drawing of them under date May 25 (*Astr. Nach.*, No. 2845). The comet does not appear to have been satisfactorily observed with the spectroscope during this period of unusual brilliancy. The outburst was soon over, and the comet speedily returned to its former faintness.

The following ephemeris (*Astr. Nach.*, No. 2838) is in continuation of that given in NATURE, vol. xxxviii. p. 186.

GEOGRAPHICAL NOTES.

THE Geographical Society of Paris have decided to avail themselves of the Universal Exhibition at Paris, next year, by convening an International Congress of the Geographical Sciences, to meet in the month of August. There will be two classes of members, subscribing respectively 40 and 20 francs, and each member will be entitled to receive a copy of the publications of the Congress and have a vote in the questions discussed at the meetings. Each Society represented at the Congress will be invited to submit a report on the voyages, explorations, and publications which have most contributed, in the country to which it belongs, to the progress of geography during the past hundred years ; the combined reports will afterwards be published with the names of their authors.

DR. H. MEYER has made some important corrections in the preliminary account of his ascent of Kilimanjaro. After verifying and correcting his barometrical observations, he admits that the previously accepted height of 18,700 feet is more accurate than that given by himself, 19,850 feet. He then refers to the dense mist which prevented him from seeing beyond a wall of inaccessible ice, 130 feet high, which his first account indicated as being the terminal point of the peak. It results from these observations that Dr. Meyer did not reach to within 820 feet of the summit of Kilimanjaro, which therefore still remains unconquered.

M. JULES BORELLI, the French traveller, who accompanied M. Rimbaud last year in his interesting journey from Antotto to Harar, is engaged in exploring the country to the south-west of Shoa. The Paris Geographical Society has received some of the results accruing from his journey from Antotto to Jiren, which is situated in 7°42′ N. latitude, and 34°35′ E. longitude. Among these results is the discovery of the sources of the River Hawash, which lie at the foot of Mount Ilfata at the extremity of the Meca range, and not near Mount Dandi, as hitherto supposed. On the summit of the latter peak the traveller found a double lake resembling in shape the figure 8, which is of considerable extent and depth ; an affluent of the Gudar, and thus of the Abbay, issues from this lake. He also discovered a deep lake at the bottom of the immense crater mountain known as Mount Harro ; the surroundings of this sheet of water are described by the traveller as of incomparable beauty. From this lake, which is named by the natives Wancit, a stream issues and joins the Walga, the source of the latter river being in the summit of Mount Harro. Dr. Traversi, the Italian explorer, made in June, 1887, an excursion into the mountainous region of Urbanagh, lying to the east of the district now being explored by M. Borelli. The chief result of this journey of Dr. Traversi is to throw light on the problem of the hydrographical systems of the Somali and Galla countries. From the summit of Mount Gafat he was able to confirm his previous observations made near the Suai Lake, with reference to the three lakes above-mentioned and their interconnection.

ON CERTAIN INEQUALITIES RELATING TO PRIME NUMBERS.

I SHALL begin with a method of proving that the number of prime numbers is infinite which is not new, but which it is worth while to recall as an introduction to a similar method, by series, which will subsequently be employed in order to prove that the number of primes of the form $4n + 3$, as also of the form $6n + 5$, is infinite.

It is obvious that the reciprocal of the product

$$\left(1 - \frac{1}{p_1}\right)\left(1 - \frac{1}{p_2}\right)\left(1 - \frac{1}{p_3}\right) \cdot \cdot \cdot \cdot \left(1 - \frac{1}{p_{N.p}}\right)$$

(where p_i means the ith in the natural succession of primes, and $p_{N.p}$ means the highest prime number not exceeding N)[1] will be equal to

$$\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \frac{1}{5} + \frac{1}{6} + \cdot \cdot \cdot \cdot + \frac{1}{N} + R,$$

and therefore greater than log N (R consisting exclusively of positive terms).

Hence

$$\left(1 + \frac{1}{p_1}\right)\left(1 + \frac{1}{p_2}\right) \cdot \cdot \cdot \cdot \left(1 + \frac{1}{p_{N.p}}\right) > M \log N,$$

where

$$M = \left(1 - \frac{1}{p_1^2}\right)\left(1 - \frac{1}{p_2^2}\right) \cdot \cdot \cdot \cdot \left(1 - \frac{1}{p_{N.p}^2}\right),$$

and is therefore greater than $\frac{2}{\pi}$.

Hence the number of terms in the product must increase indefinitely with N.

By taking the logarithms of both sides we obtain the inequality

$$S_1 - \tfrac{1}{2}S_2 + \tfrac{1}{3}S_3 - \tfrac{1}{4}S_4 + \cdot \cdot \cdot \cdot > \log \log N,$$

where in general S_i means the sum of inverse ith powers of all the primes not exceeding N ; and accordingly is finite, except when $i = 1$, for any value of N. We have therefore

$$S_1 > \log \log N + \text{Const.}$$

The actual value of S_1 is observed to differ only by a limited quantity from the second logarithm of N, but I am not aware whether this has ever been strictly proved.

Legendre has found that for large values of N

$$(1 - \tfrac{1}{3})(1 - \tfrac{1}{5}) \cdot \cdot \cdot \cdot \left(1 - \frac{1}{p_{N.p}}\right) = \frac{1{\cdot}104}{\log N}.$$

Consequently

$$\left(1 - \frac{1}{p_1}\right)\left(1 - \frac{1}{p_2}\right) \cdot \cdot \cdot \cdot \left(1 - \frac{1}{p_{N.p}}\right) = \frac{{\cdot}552}{\log N}.$$

This would show that the value of our R bears a finite ratio to log N ; calling it θ log N we obtain, according to Legendre's formula,

$$\frac{1}{1 + \theta} = {\cdot}552, \text{ which gives } \theta = {\cdot}811,$$

so that the nebulous matter, so to say, in the expansion of the reciprocal of the product of the differences between unity and the reciprocals of all the primes not exceeding a given number, stands in the relation of about 4 to 5 to the condensed portion consisting of the reciprocals of the natural numbers.

I will now proceed to establish similar inequalities relating to prime numbers of the respective forms $4n + 3$ and $6n + 5$.

Beginning with the case $4n + 3$, I shall use q_j to signify the jth in the natural succession of primes of the form $4n + 3$, and $q_{N.q}$ to signify the highest q not exceeding N, N.q itself signifying the number of q's not exceeding N.

[1] N.p itself of course denotes in the above notation the number of primes (p) not exceeding N.

Let us first, without any reference to convergence, consider the product obtained by the usual mode of multiplication of the infinite series

$$S = 1 - \tfrac{1}{3} + \tfrac{1}{5} - \tfrac{1}{7} + \tfrac{1}{9} - \ldots \textit{ ad inf.}$$

by the product

$$\frac{1}{1-\frac{1}{2}} \cdot \frac{1+\frac{1}{q_1}}{1-\frac{1}{q_1}} \cdot \frac{1+\frac{1}{q_2}}{1-\frac{1}{q_2}} \cdot \frac{1+\frac{1}{q_3}}{1-\frac{1}{q_3}} \ldots \textit{ ad inf.}$$

It is clear that the effect of the multiplication of S by the numerator of the above product will be to deprive the series S of all its negative terms. Then the effect of dividing by the denominator of the product, with the exception of the factor $1 - \frac{1}{2}$, will be to restore all the obliterated terms, but with the sign + instead of −. Lastly, the effect of multiplying by the reciprocal of $(1 - \frac{1}{2})$ will be to supply the even numbers that were wanting in the denominators of the terms of S, and we shall thus get the indefinite series

$$1 + \tfrac{1}{2} + \tfrac{1}{3} + \tfrac{1}{4} + \ldots \textit{ ad inf.}$$

Call now

$$Q_N = \frac{1}{1-\frac{1}{2}} \cdot \frac{1+\frac{1}{q_1}}{1-\frac{1}{q_1}} \cdot \frac{1+\frac{1}{q_2}}{1-\frac{1}{q_2}} \ldots \frac{1+\frac{1}{q_{N.q}}}{1-\frac{1}{q_{N.q}}}.$$

Q_N, which is finite when N is finite, may be expanded into an infinite aggregate of positive terms, found by multiplying together the series

$$1 + \tfrac{1}{2} + \tfrac{1}{4} + \tfrac{1}{8} + \ldots$$
$$1 + \frac{2}{q_1} + \frac{2}{q_1^2} + \frac{2}{q_1^3} + \ldots$$
$$1 + \frac{2}{q_2} + \frac{2}{q_2^2} + \frac{2}{q_2^3} + \ldots$$
$$\ldots\ldots\ldots\ldots\ldots\ldots$$
$$\ldots\ldots\ldots\ldots\ldots\ldots$$
$$1 + \frac{2}{q_{N.q}} + \frac{2}{q_{N.q}^2} + \frac{2}{q_{N.q}^3} + \ldots$$

Let

$$S_N = 1 - \tfrac{1}{3} + \tfrac{1}{5} - \tfrac{1}{7} + \tfrac{1}{9} - \tfrac{1}{11} + \ldots \pm \frac{1}{N},$$

then from what has been said it is obvious that we may write

$$Q_N S_N = 1 + \tfrac{1}{2} + \tfrac{1}{3} + \tfrac{1}{4} + \ldots + \frac{1}{N} + V - R,$$

where V and R may be constructed according to the following rule: Let the denominator of any term in the aggregate Q_N be called t, and let θ be the smallest odd number which, multiplied by t, makes $t\theta$ greater than N; then if θ is of the form $4n + 1$ it will contribute to V a portion represented by the product of the term by some portion of the series S_N of the form

$$\frac{1}{\theta} - \frac{1}{\theta+2} + \frac{1}{\theta+4} - \ldots$$

and if θ is of the form $4n + 3$ it will contribute to − R a portion equal to the term multiplied by a series of the form

$$-\frac{1}{\theta} + \frac{1}{\theta+2} - \frac{1}{\theta+4} + \ldots$$

Hence R is made up of the sum of products of portions of the aggregate Q_N multiplied respectively by the series

$$\tfrac{1}{3} - \tfrac{1}{5} + \tfrac{1}{7} - \tfrac{1}{9} + \tfrac{1}{11} - \tfrac{1}{13} + \ldots$$
$$\tfrac{1}{7} - \tfrac{1}{9} + \tfrac{1}{11} - \tfrac{1}{13} + \ldots$$
$$\tfrac{1}{11} - \tfrac{1}{13} + \ldots$$

of which the greatest is obviously the first, whose value is $1 - S_N$.

Consequently R must be less than the total aggregate Q_N multiplied by $1 - S_N$.

Therefore

$$Q_N S_N + Q_N(1 - S_N) > 1 + \tfrac{1}{2} + \tfrac{1}{3} + \tfrac{1}{4} + \ldots + \frac{1}{N} > \log N,$$

i.e.

$$Q_N > \log N,$$

from which it follows that when N increases indefinitely the number of factors in Q_N also increases indefinitely, and there must therefore be an infinite number of primes of the form $4n + 3$.

Denoting by M_N the quantity

$$\left(1 - \frac{1}{q_1^2}\right)\left(1 - \frac{1}{q_2^2}\right) \ldots \left(1 - \frac{1}{q_{N.q}^2}\right)$$

we obtain the inequality

$$\left(1 + \frac{1}{q_1}\right)^2\left(1 + \frac{1}{q_2}\right)^2 \ldots \left(1 + \frac{1}{q_{N.q}}\right)^2 > \tfrac{1}{2}M_N \log N,$$

and taking the logarithms of both sides

$$\Sigma_1 - \tfrac{1}{2}\Sigma_2 + \tfrac{1}{3}\Sigma_3 - \ldots > \tfrac{1}{2}\log\log N + \tfrac{1}{2}\log M_N - \tfrac{1}{2}\log 2,$$

where in general Σ_i denotes the sum of the ith powers of the reciprocals of all prime numbers of the form $4n + 3$ not surpassing N.

Hence it follows that $\Sigma_1 > \frac{1}{2}\log\log N$.

If we could determine the ultimate ratio of the sum of those terms of Q_N whose denominators are greater than N to the total aggregate, and should find that μ, the limiting value of this ratio, is not unity, then the method employed to find an inferior limit would enable us also to find a superior limit to Q_N; for we should have $V < \mu Q_N$ added to the sum of portions of what remains of the aggregate when μQ_N is taken from it multiplied respectively by the several series

$$\tfrac{1}{5} - \tfrac{1}{7} + \tfrac{1}{9} - \tfrac{1}{11} + \tfrac{1}{13} - \tfrac{1}{15} + \ldots \textit{ ad inf.}$$
$$\tfrac{1}{9} - \tfrac{1}{11} + \tfrac{1}{13} - \tfrac{1}{15} + \ldots \textit{ ad inf.}$$
$$\tfrac{1}{13} - \tfrac{1}{15} + \ldots \textit{ ad inf.}$$

the total value of the sum of which products would evidently be less than

$$(1 - \mu)(S - 1 + \tfrac{1}{3})Q_N.$$

Hence the total value of V would be less than

$$\mu Q_N S + (1 - \mu)Q_N(S - \tfrac{2}{3}),$$

i.e. less than

$$Q_N S - \tfrac{2}{3}(1 - \mu)Q_N,$$

and consequently we should have

$$\tfrac{2}{3}(1 - \mu)Q_N < \log N,$$

i.e.

$$Q_N < \frac{3}{2(1 - \mu)} \log N.$$

From which we may draw the important conclusion that if μ is less than 1, *i.e.* if when N is infinite the portion of the aggregate $S_N Q_N$ comprising the terms whose denominators exceed N does not become infinitely greater than the remaining portion, the sum of the reciprocals of all the prime numbers of the form $4n + 3$ not exceeding N would differ by a limited quantity from half the second logarithm of N.

A precisely similar treatment may be applied to prime numbers of the form $6n + 5$. We begin with making

$$S_N = 1 - \tfrac{1}{5} + \tfrac{1}{7} - \tfrac{1}{11} + \tfrac{1}{13} - \tfrac{1}{17} + \tfrac{1}{19} - \ldots$$

We write

$$Q_N = \frac{1}{1-\frac{1}{2}} \cdot \frac{1}{1-\frac{1}{3}} \cdot \frac{1+\frac{1}{r_1}}{1-\frac{1}{r_1}} \cdot \frac{1+\frac{1}{r_2}}{1-\frac{1}{r_2}} \ldots \frac{1+\frac{1}{r_{N.r}}}{1-\frac{1}{r_{N.r}}}$$

We make

$$Q_N S_N = 1 + \tfrac{1}{2} + \tfrac{1}{3} + \tfrac{1}{4} + \ldots + \frac{1}{N} + V - R.$$

We prove as before that

$$R < (1 - S)Q_N,$$

and thus obtain

$$Q_N > \log N,$$

and then putting

$$M_N = \left(1 - \frac{1}{r_1^2}\right)\left(1 - \frac{1}{r_2^2}\right) \ldots \left(1 - \frac{1}{r_{N.r}^2}\right),$$

and finally noticing that

$$\frac{1}{1-\frac{1}{2}} \cdot \frac{1}{1-\frac{1}{3}} = 3,$$

we obtain

$$\left(1 + \frac{1}{r_1}\right)^2\left(1 + \frac{1}{r_2}\right)^2 \ldots \left(1 + \frac{1}{r_{N.r}}\right)^2 > \tfrac{1}{3}M_N \log N.$$

Taking the logarithms of both sides of the equation, we find

$$\Theta_1 - \tfrac{1}{2}\Theta_2 + \tfrac{1}{3}\Theta_3 - \ldots > \tfrac{1}{2}\log\log N + \tfrac{1}{2}\log M_N - \tfrac{1}{2}\log 3,$$

where Θ_i means the sum of ith powers of the reciprocals of all the prime numbers, not exceeding N, of the form $6n + 5$.

Either from this equation or from the one from which it is derived it at once follows that the number of primes of the form $6n + 5$ is greater than any assignable limit.

Parallel to what has been shown in the preceding case, if it could be ascertained that the sum of the terms of the aggregate Q_N whose denominations do not exceed N bears a ratio which becomes indefinitely small to the total aggregate, it would follow by strict demonstration that the sum of the reciprocals of the primes of the form $6n + 5$ inferior to N would always differ by a limited quantity from the half of the second logarithm of N.

It is perhaps worthy of remark that the infinitude of primes of the forms $4n + 3$ and $6n + 5$ may be regarded as a simple rider to Euclid's proof (Book IX., Prop. 20) of the infinitude of the number of primes in general.

The point of this is somewhat blunted in the way in which it is presented in our ordinary text-books on arithmetic and algebra. What Euclid gives is something more than this:[1] his statement is, "There are more prime numbers than any proposed multitude (πλῆθος) of prime numbers"; which he establishes by giving a formula for finding at least one more than any proposed number. He does not say, as our text-book writers do, "if possible let A, B, ... C be *all* the prime numbers," &c., but simply that if A, B, ... C are *any* proposed prime numbers, one or more additional ones may be found by adding unity to their product which will either itself be a prime number, or contain at least one additional prime; which is all that can correctly be said, inasmuch as the augmented product may be the power of a prime.

Thus from one prime number arbitrarily chosen, a progression may be instituted in which one new prime number at least is gained at each step, and so an indefinite number may be found by Euclid's formula: *e.g.* 17 gives birth to 2 and 3; 2, 3, 17 to 103; 2, 3, 17, 103 to 7, 19, 79; and so on.

We may vary Euclid's mode of generation and avoid the transcendental process of decomposing a number into its prime factors by using the more general formula, $a, b, \ldots c + 1$, where $a, b, \ldots c$, are any numbers relatively prime to each other; for this formula will obviously be a prime number or contain one or more distinct factors relatively prime to $a, b, \ldots c$.

The effect of this process will be to generate a continued series of numbers all of which remain prime to each other: if we form the progression

$$a,\ a+1,\ a^2+a+1,\ a(a+1)(a^2+a+1)+1,\ \ldots$$

and call these successive numbers

$$u_1,\ u_2,\ u_3,\ u_4,\ \ldots$$

we shall obviously have

$$u_{x+1} = u_x^2 - u_x + 1.$$

It follows at once from Euclid's point of view that no primes contained in any term up to u_x can appear in u_{x+1}, so that all the terms must be relatively prime to each other. The same consequence follows *a posteriori* from the scale of relation above given; for, as I had occasion to observe in the *Comptes rendus* for April 1888, if dealing only with rational integer polynomials,

$$\phi(x) = (x - a)f(x) + a,$$

then, whatever value, c, we give to x, no two forms $\phi^i(c)$, $\phi^j(c)$ can have any common measure not contained in a: in this case $\phi(x) = (x-1)x + 1$; so that $\phi^i(c)$ and $\phi^j(c)$ must be relative primes for all values of i and j.[2]

It is worthy of remark that all the primes, other than 3, implicitly obtained by this process will be of the form $6i + 1$.

Euclid's own process, or the modified and less transcendental one, may be applied in like manner to obtain a continual succession of primes of the form $4n + 3$ and $6n + 5$.

[1] Whereas the English elementary book writers content themselves with showing that to suppose the number of primes finite involves an absurdity, Euclid shows how from any given prime or primes to generate an infinite succession of primes.

[2] Another theorem of a similar kind is that, whatever integer polynomial $\phi(x)$ may be, if i, j have for their greatest common measure k, then $\phi^k[\phi(0)]$ will be the greatest common measure of $\phi^i[\phi(0)]$, $\phi^j[\phi(0)]$.

As regards the former, we may use the formula

$$2 \cdot a \cdot b \ldots c + 1$$

(where $a, b, \ldots c$ are any "proposed" primes of the form $4n + 3$), which will necessarily be of the form $4n + 3$, and must therefore contain *one* factor at least of that form.

As regards the latter, we may employ the formula

$$3 \cdot a \cdot b \ldots c + 2$$

(where $a, b, \ldots c$ are each of the form $6n + 5$), which will necessarily itself be, and therefore contain *one* factor at least, of that form.

The scale of relation in the first of these cases will be, as before,

$$u_{x+1} = u_x^2 - u_x + 1;$$

so that each term in the progression, abstracting 3, will be of the form $4i + 3$ and $6j + 1$ conjointly, and consequently of the form $12n + 7$; as *e.g.*,

$$3,\ 7,\ 43,\ 1807,\ \ldots$$

In the latter case the scale of relation is

$$u_{x+1} = u_x^2 - 2u_x + 2,$$

which is of the form $(u_x - 2)u_x + 2$. It is obvious that in each progression at each step one new prime will be generated, and thus the number of ascertained primes of the given form go on indefinitely increasing, as also might be deduced *a posteriori* by aid of the general formula above referred to from the scale of relation applicable to each. Each term in the second case (the term 3, if it appears, excepted) will be simultaneously of the form $6i - 1$ and $4j + 1$, and consequently of the form $12n + 5$, as in the example 5, 17, 257, 65537, ...

The same simple considerations *cease* to apply to the genesis of primes of the forms $4n + 1$, $6n + 1$. We may indeed apply to them the formulæ

$$(2 \cdot a \cdot b \ldots c)^2 + 1 \text{ and } 3(a \cdot b \ldots c)^2 + 1$$

respectively, but then we have to draw upon the theory of quadratic forms in order to learn that their divisors are of the form $4n + 1$ and $6n + 1$ respectively.

Of course the difference in their favour is that in their case *all* the divisors locked up in the successive terms of the two progressions respectively are of the prescribed form; whereas in the other two progressions, whose theory admits of so much simpler treatment, we can only be assured of the presence of *one* such factor in each of the several terms.

Euler has given the values of two infinite products, without any evidence of their truth except such as according to the lax method of dealing with series without regard to the laws of convergence prevalent in his day, and still held in honour in Cambridge down to the times of Peacock, De Morgan, and Herschel inclusive (and this long after Abel had justly denounced the use of divergent series as a crime against reason), was erroneously supposed to amount to a proof, from which the same consequences may be derived as shown in the foregoing pages, and something more besides.[1] These two theorems are—

$$(1)\quad \frac{3}{3+1} \cdot \frac{5}{5-1} \cdot \frac{7}{7+1} \cdot \frac{11}{11+1} \cdot \frac{13}{13-1} \cdot \ldots = \frac{\pi}{4}$$

(where, corresponding to the primes 3, 7, 11, ... of the form $4n + 3$, the factors of the product on the left are

$$\frac{3}{3+1},\ \frac{7}{7+1},\ \frac{11}{11+1},\ \ldots$$

all of them with the sign + in the denominator; while the fractions corresponding to primes of the form $4n + 1$ have the − sign in their denominators).

$$(2)\quad \frac{5}{5+1} \cdot \frac{7}{7-1} \cdot \frac{11}{11+1} \cdot \frac{13}{13-1} \cdot \frac{17}{17+1} \cdot \ldots = \frac{\pi}{2}\sqrt{3}$$

where, as in the previous product, the sign in the denominator of each fraction depends on the form of the prime to which it corresponds (being + for primes of the form $6n - 1$, and − for primes of the form $6n + 1$).

[1] It follows from the first of these theorems that with the understanding that no denominator is to exceed n (an indefinitely great number), $(1 + \frac{1}{3})(1 + \frac{1}{7})(1 + \frac{1}{11})(1 + \frac{1}{19}) \ldots$ bears a finite ratio to $(1 + \frac{1}{5})(1 + \frac{1}{13})(1 + \frac{1}{17}) \ldots$ so that as their *product* is known to be infinite, each of these two partial products must be separately infinite; in like manner from Euler's second theorem a similar conclusion may be inferred in regard to each of the two products $(1 + \frac{1}{5})(1 + \frac{1}{11})(1 + \frac{1}{17})(1 + \frac{1}{23})(1 + \frac{1}{29})(1 + \frac{1}{41}) \ldots$ and $(1 + \frac{1}{7})(1 + \frac{1}{13})(1 + \frac{1}{19})(1 + \frac{1}{31}) \ldots$

Dr. J. P. Gram (*Mémoires de l'Académie Royale de Copenhague*, 6me. série, vol. ii. p. 191) refers to a paper by Mertens ("Ein Beitrag zur analytischen Zahlentheorie," *Borchardt's Journal*, Bd. 78), as one in which the truth of the first of the two theorems is demonstrated—"fuldstoendigt Bevis af Mertens" are Gram's words.[1]

Assuming this to be the case, we shall easily find when N is indefinitely great, so that S_N becomes $\frac{\pi}{4}$,

$$Q_N S_N = \frac{1}{(1-\frac{1}{2})(1-\frac{1}{3})\ldots\ldots\left(1-\frac{1}{N}\right)},$$

which, according to Legendre's empirical law (Legendre, "Théorie des Nombres," 3rd edition, vol. ii. p. 67, art. 397), is equal to $\frac{2\log N}{K}$, where $K = 1{\cdot}104$; and as we have written $Q_N S_N = \log N + (V - R)$, we may deduce, upon the above assumptions,

$$V - R = \left(\frac{2}{K} - 1\right)\log N = 0{\cdot}811\ldots\ldots\log N.$$

R, we know, is demonstrably less than $\left(1 - \frac{\pi}{4}\right)\log N$, consequently V must be less than $(0{\cdot}812 + 0{\cdot}215)\log N$, *i.e.* less than $1{\cdot}027 \log N$, and *a fortiori* the portion of the omnipositive aggregate Q_N, which consists of terms whose denominators exceed N, when N is indefinitely great, cannot be less than $\frac{4}{\pi}\left(1 - \frac{\pi}{4}\right)\log N$, *i.e.* $0{\cdot}273 \log N$.

Before concluding, let me add a word on Legendre's empirical formula for the value of

$$(1-\tfrac{1}{3})(1-\tfrac{1}{5})\ldots\ldots\left(1-\frac{1}{p_{N.p}}\right),$$

referred to in the early part of this article.

If N is any odd number, the condition of its being a prime number is that when divided by any odd prime less than its own square root, it shall not leave a remainder zero. Now if N (an unknown odd number) is divided by p, its remainder is equally likely to be 0, 1, 2, 3, ... or $(p - 1)$. Hence the chance that it is not divisible by p is $\left(1 - \frac{1}{p}\right)$, and, if we were at liberty to regard the like thing happening or not for any two values of p within the stated limit as independent events, the expectation of N being a prime number would be represented by

$$(1-\tfrac{1}{3})(1-\tfrac{1}{5})(1-\tfrac{1}{7})(1-\tfrac{1}{11})\ldots\ldots\left(1-\frac{1}{p_{N^{\frac{1}{2}}.p}}\right),$$

which, according to the formula referred to, for infinitely large values of N is equal to $\frac{1{\cdot}104}{\log N^{\frac{1}{2}}}$. It is rather more convenient to regard N as entirely unknown instead of being given as odd, on which supposition the chance of its being a prime would be $\frac{1{\cdot}104}{2\log N^{\frac{1}{2}}}$ or $\frac{1{\cdot}104}{\log N}$.

Hence for very large values of N the sum of the logarithms of all the primes inferior to N might be expected to be something like $(1{\cdot}104)N$. This does not contravene Tchebycheff's formula (Serret, "Cours d'Algèbre Supérieure," 4me ed., vol. ii. p. 233), which gives for the limits of this sum AN and BN, where $A = 0{\cdot}921292$, and $B = \frac{6A}{5} = 1{\cdot}10555$; but does contravene the narrower limits given by my advance upon Tchebycheff's method (see *Am. Math. Journal*, vol. iv. Part 3), according to which for A, B, we may write A_1, B_1, where

$$A_1 = 0{\cdot}921423,\ B_1 = 1{\cdot}076577.$$[1]

That the method of probabilities *may* sometimes be successfully applied to questions concerning prime numbers I have shown reason for believing in the two tables published by me in the *Philosophical Magazine* for 1883.[2]

New College, June 10. J. J. SYLVESTER.

[1] It always seems to me absurd to speak of a complete proof, or of a theorem being rigorously demonstrated. An incomplete proof is no proof, and a mathematical truth not rigorously demonstrated is not demonstrated at all. I do not mean to deny that there are mathematical truths, morally certain, which defy and will probably to the end of time continue to defy proof, as, *e.g.*, that every indecomposable integer polynomial function must represent an infinitude of primes. I have sometimes thought that the profound mystery which envelops our conceptions relative to prime numbers depends upon the limitation of our faculties in regard to time, which like space may be in its essence poly-dimensional, and that this and such sort of truths would become self-evident to a being whose mode of perception is according to *superficially* as distinguished from our own limitation to *linearly* extended time.

[1] Viz. $A_1 = \frac{51072}{50999}A$, and $B_1 = \frac{59595}{50999}A$, the values of which are incorrectly stated in the memoir. Strange to say, Dr. Gram, in his prize essay, previously quoted, on the number of prime numbers under a given limit, has omitted all reference to this paper in his bibliographical summary of the subject, which is only to be accounted for by its having escaped his notice; a narrowing of the asymptotic limits assigned to the sum of the logarithms of the prime numbers series being the most notable fact in the history of the subject since the publication of Tchebycheff's memoir. Subjectively, this paper has a peculiar claim upon the regard of its author, for it was his meditation upon the two simultaneous difference-equations which occur in it that formed the starting-point, or incunabulum, of that new and boundless world of thought to which he has given the name of Universal Algebra. But, apart from this, that the superior limit given by Tchebycheff as $1{\cdot}1055$ should be brought down by a more stringent solution of his own inequalities to only $1{\cdot}076577$—in other words, that the excess above the probable mean value (unity) should be reduced to little more than ⅔rds of its original amount—is in itself a surprising fact. Perhaps the numerous (or innumerable) misprints and arithmetical miscalculations which disfigure the paper may help to account for the singular neglect which it has experienced. It will be noticed that the mean of the limits of Tchebycheff is $1{\cdot}01342$, the mean of the new limits being $0{\cdot}99900$. The excess in the one case above and the defect in the other below the probable true mean are respectively $0{\cdot}01342$ and $0{\cdot}00100$.

[2] A principle precisely similar to that employed above if applied to determining the number of reduced proper fractions whose denominators do not exceed a given number n, leads to a correct result. The expectation of two numbers being prime to each other will be the product of the expectations of their not being each divisible by any the same prime number. But the probability of one of them being divisible by i is $\frac{1}{i}$, and therefore of two of them being not each divisible by i is $\frac{1}{i^2}$. Hence the probability of their having no common factor is

$$(1-\tfrac{1}{4})(1-\tfrac{1}{9})(1-\tfrac{1}{25})(1-\tfrac{1}{49})\ldots\ldots\ ad\ inf.,\ i.e.\ \text{is}\ \frac{6}{\pi^2}.$$

If, then, we take two sets of numbers, each limited to n, the probable number of relatively prime combinations of each of one set with each of the other should be $\frac{6n^2}{\pi^2}$, and the number of reduced proper fractions whose denominators do not exceed n should be the half of this or $\frac{3n^2}{\pi^2}$. I believe M. Césaro has claimed the prior publication of this mode of reasoning, to which he is heartily welcome. The number of these fractions is the same thing as the sum of the *totients* of all numbers not exceeding n. In the *Philosophical Magazine* for 1883 (vol. xv. p. 251), a table of these sums of totients has been published by me for all values of n not exceeding 500, and in the same year (vol. xvi p. 231) the table was extended to values of n not exceeding 1000. In every case without any exception the estimated value of this totient sum is found to be intermediate between

$$\frac{3n^2}{\pi^2} \text{ and } \frac{3(n+1)^2}{\pi^2}.$$

Calling the totient sum to n, $T(n)$, I stated the exact equation

$$T(n) + T\left(\frac{n}{2}\right) + T\left(\frac{n}{3}\right) + T\left(\frac{n}{4}\right) + \ldots\ldots = \frac{n^2+n}{2},$$

from which it is capable of proof, without making any assumption as to the form of Tn, that its asymptotic value is $\frac{3n^2}{\pi^2}$. The functional equation itself is merely an integration (so to say) of the well-known theorem that any number is equal to the sum of the totients of its several divisors. The introduction to these tables will be found very suggestive, and besides contains an interesting bibliography of the subject of Farey series (*suites de Farey*), comprising, among other writers upon it, the names of Cauchy, Glaisher, and Sir G. Airy, the last-named as author of a paper on toothed wheels, published, I believe, in the "Selected Papers" of the Institute of Mechanical Engineers. The last word on the subject, as far as I am aware, forms one of the *interludes*, or rather the *postscript*, to my "Constructive Theory of Partitions," published in the *American Journal of Mathematics*.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 3.—"Electro-Chemical Effects on Magnetizing Iron." Part II. By Thomas Andrews, F.R.S.E. Communicated by Prof. G. G. Stokes, P.R.S.

The present paper contains the results of a further study of the electro-chemical effects observed between a magnetized and an unmagnetized bar when in circuit in certain electrolytes, recorded in Part I. of this research. The method of experimentation was generally similar to that pursued and described in Part I., though it was necessary to introduce numerous modifications of detail and also new modes of experimentation. The bars experimented on were of specially prepared wrought-iron and cast-steel; all the rods were finely polished, and the general physical properties of the metals are given in Table B. Steel bars were employed in some of the experiments, because after magnetization by the coil their subsequent influence as permanent magnets could be observed. The reagents employed as electrolytes consisted of various solutions of bromine, ferric chloride, and chlorine water, ferrous sulphate, ferric chloride, cupric chloride, cupric sulphate, cupric nitrate, cupric acetate, cupric bromide, nickel chloride, hydrochloric, acid, nitric acid, and potassium chlorate. A pair of bars in each experiment were immersed as elements in the solution in the special apparatus employed, in circuit also with a delicate galvanometer, and after normal galvanic equilibrium had been obtained the bar within the coil was magnetized for various periods and the magneto-chemical effect observed. It was found to vary with the nature of the metal and solution employed, and also with the extent of the magnetization of the metals. The average results of many repeated experiments are given in numerous detailed tables, and it was generally found that a magnetized bar became electro-positive to an unmagnetized one. In Parts I. and II. a total of near 600 iron and steel bars have been experimented upon. Experiments were also made showing that local currents were developed in a magnetized bar between the more highly and less magnetized parts thereof, when the rod was immersed in suitable solutions acting chemically upon it.

Interesting experiments have also been made in connection with the influence of magnetization on the action of strong nitric acid on iron and steel. In course of the research the results of an extensive quantitative study of magneto-chemical phenomena have been recorded, the effect in connection with a considerable variety of typical reagents having been carefully observed; with some reagents the effect was found to be comparatively small, in other instances it was somewhat considerable. The general conclusion was that under the conditions recorded a magnetized bar was electro-positive to an unmagnetized one, when the two were immersed in suitable solutions, and that the extent of the result was in some degree dependent both on the nature and strength of the solution, and also on the extent of the magnetization of the metal.

June 7.—"Note on the Volumetric Determination of Uric Acid." By A. M. Gossage, B.A. Oxon.

It seemed improbable that the method recently proposed by Dr. Haycraft for the volumetric determination of uric acid in urine could be accurate, since both Salkowski and Maly had previously shown that the precipitate of silver urate obtained from urine contains variable quantities of other urates. To test the method, I examined samples of various urines both by his method and by that of Salkowski, which is universally acknowledged to be the most trustworthy. The mean percentages of uric acid found were as follow:—

Experiment	I.	II.	III.	IV.	V.
Haycraft's method	0·108	0·076	0·082	0·072	0·108
Salkowski's method	0·084	0·035	0·051	0·035	0·084

The results obtained by Haycraft's method were always considerably higher than those obtained by Salkowski's. The reason of this is that Dr. Haycraft has assumed that the silver precipitate from urine consists of a urate containing only 1 atom of silver in the molecule, whereas the proportion of silver in silver urate corresponds more nearly to 2 atoms in the molecule. Assuming, then, that there are 2 atoms of silver in all the molecules of the urate, and dividing the results obtained by Haycraft's method by two, we see that the results so obtained are usually lower than those obtained by Salkowski's method, and that the proportion between the results by the two methods varies, as would be expected from Salkowski's researches.

EDINBURGH.

Royal Society, June 4.—Dr. John Murray, Vice-President, in the chair.—Dr. G. Sims Woodhead exhibited a series of photographs of large sections of the lung.—A paper by the Astronomer-Royal for Scotland on Scottish meteorology for the last thirty-two years was read.—Dr. E. Sang read a paper on John Leslie's computation of the ratio of the diameter to the circumference of a circle.—A paper by Lord Maclaren on the figure of aplanatic lenses was read.—Prof. Tait submitted some quaternion notes.

June 18.—The Hon. Lord Maclaren, Vice-President, in the chair.—The Secretary exhibited M. Amagat's photographs of the crystallization of chloride of carbon under pressure alone.—A paper by Prof. W. Carmichael McIntosh and Mr. E. E. Prince, St. Andrews' Marine Laboratory, was communicated.—A paper by Prof. Anglin on certain theorems mainly connected with alternants, was read.—Prof. Haycraft and Dr. R. T. Williamson gave a demonstration of a method, which can be used chemically, for estimating quantitatively the alkalinity of the blood.—A preliminary notice of a paper by Dr. G. N. Stewart on electrolytic decomposition of proteid substances was submitted.—Papers by Dr. A. B. Griffiths, on the Malpighian tubules of *Libellula depressa*, and on a fungoid disease in the roots of *Cucumis sativa*, were communicated.

PARIS.

Academy of Sciences, July 2.—M. Janssen, President, in the chair.—Reply to Mr. Douglas Archibald's strictures on the subject of storms, by M. H. Faye. The storm laws, as established by the observations of Capper, Piddington, Reid, and Redfield, are declared to be one of the greatest discoveries of the century, and their truth is here vindicated against the recent attacks of Prof. Loomis, Dr. Meldrum, and especially Mr. E. Douglas Archibald, in NATURE for June 14 (p. 149). Archibald's diagram of the Manilla cyclone of October 20, 1882, is here reproduced, and it is contended that these highly characteristic phenomena can be explained only by admitting a *descending* motion in the central part of the cyclone. But on the opposite supposition it is precisely here that the *ascending* current should be strongest, for this central region corresponds exactly to the minimum of barometric pressure. The error in this theory of his opponents is attributed to a confusion between two quite distinct kinds of depressions, a confusion which has for fifty years impeded the progress of meteorological science and increased the perils of navigation.—On the cultivation of Bœmaria in Provence, by M. Naudin. The author reports that the white species (*B. nivea*), lately introduced from China, thrives well in the Antibes district, where the green variety (*B. utilis*) has long been acclimatized. The foliage makes excellent fodder for cattle.—Automatic control of the velocity in machinery of variable action, by M. H. Léauté. An apparatus, the result of many years' study, is here described, by means of which the action of engines may easily be regulated, even when required to work at varying rates of speed.—On a compass enabling the observer to find the meridian on land or water despite the disturbing influence of iron, by M. Bisson. An ingenious apparatus is described by means of which the compass may be prevented from deviating more than one-tenth of a millimetre, even in the neighbourhood of iron. It has been tested with satisfactory results on board several French ironclads, and works equally well by land or sea.—On the snows, ice, and waters of Mars, by M. Flammarion. In reply to some recent remarks on the meteorological condition of this planet, it is pointed out that the varying state of the polar ice-caps has long been carefully observed by Maedler, Schiaparelli, and others, the inference being that Mars is not in a state of glaciation. On the contrary its temperature is equal to, if not higher, than that of the earth, and its polar snows melt periodically to a far greater extent than on our planet.—On the graphic representation of numerical divisors, by M. Saint-Loup. By adopting a rectangular distribution of the numerals, the author arrives at some practical results on the general grouping of the prime numbers.—On the determination of the constants and of the dynamic coefficient of elasticity for steel, by M. E. Mercadier. By the method already indicated (*Comptes rendus*, July and August, 1887), the author here determines the relation $\frac{\lambda}{\mu}$ of the constants for steel. In a future paper will be given the results of the experiments undertaken to determine the coefficients of electricity.—On the mechanism of electrolysis by the process of alternative currents, by MM. J. Chappuis and G. Maneuvrier. The recognized impossibility of electrolysing the sulphate of copper by alternative currents is explained by the theory that the copper deposited on each electrode by one of the currents is immediately dissipated by the inverse current. This explanation is here justified by the authors' experiments, which render *visible* the decomposition of the sulphate of copper, as they had previously done for acidulated water. From this experimental study they hope to deduce the general principles for the practical application of alternative currents in the process of electrolysis.—Application of Carnot's principle to endothermic reactions, by M. Pellat. By distinguishing between the temperature of the bodies giving rise to the endothermic reaction and that of the source supplying in the form of heat the energy needed for the reaction, the author is led by the application of Carnot's principle to a law analogous to that of Potier, but of a more general character.—On the hydrochlorate of cupric chloride, by M. Paul Sabatier. The author admits the priority of M. Engel's researches on the properties and preparation of this substance, but points out that this chemist gives it a very different composition from that which he has himself obtained, and which is represented by the formula CuCl, HCl, 5HO.—On the artificial reproduction of the micas and of scapolite, by M. Doelter. A process is described, by means of which the author has artificially reproduced the chief minerals of the mica group, as well as of natural scapolite. He has already effected the synthesis of biotite, phlogopite, muscovite, and lepidolite (zinnwaldite variety).—Fresh physiological researches on the organic substance which has the property of hydrogenating sulphur, by M. J. de Rey-Pailhade. During his further study of this substance, to which he has given the name of philothion, the author has determined several new facts, amongst others that when the yeast is treated by reagents, the death of the organism always precedes the destruction of this organic substance. Philothion is generated by the physiological development of the yeast, and combines with sulphur according to an equation of which sulphuretted hydrogen is a factor. Acting as a diastase, it adds a fresh proof to M. Berthelot's theory of fermentation. Lastly, it is the first known instance of a substance extracted from a living organism which has the property of hydrogenizing sulphur.—Prof. Langley has been elected by a large majority to succeed the late M. Roche as Corresponding Member of the Academy on the Section of Astronomy.

BERLIN.

Physiological Society, June 22.—Prof. du Bois Reymond, President, in the chair.—Dr. H. Virchow spoke on the blood-vessels of the eye in Carnivora as worked at by Bellarminoff under his direction. The communication was illustrated by drawings and the exhibition of preparations. The points of most general interest which stand out from among the mass of details in this research are that the blood-vessels of the eye have a tendency to form rings from which a large number of fine branches pass posteriorly; further that the arrangement is often very different in different classes of animals, thus, for instance, the course of the arteries in the eye of a dog as compared with that of a rabbit is such that the dog's eye must be turned through an angle of 180° in order to make the course of its arteries correspond with that of the rabbit's eye.—Dr. Heymans communicated the results of his researches on the nerve-endings in the unstriated muscle-fibres of the medicinal leech. In the alimentary canal of the Hirudinea the muscle-fibres are placed both longitudinally and circularly; they consist of a contractile sheath and a protoplasmic axis containing the nucleus, and either have pointed ends or else divide into two or more branches, each of which then ends in a point. The muscle-fibres are separated from each other by large interstitial spaces filled with connective tissue, in which the nerve-plexus lies and sends fine nerve-branches into the muscle-fibres. The nerves end partly as extremely fine filaments and partly as round, flattened end-plates, and in no case does the nerve-ending penetrate the contractile sheath of the fibre so as to come into connection with the protoplasmic axis. In the vascular system of the leech the muscular layers are principally disposed in a circular fashion, but frequently the speaker noticed that at some point or another a circular fibre divided itself into two branches, and that the latter were then bent through a right angle so as now to pass in a longitudinal course in the wall of the blood-vessel. The nerve-endings in the fibres of the vascular system are the same as in those of the alimentary canal. Similarly, the muscle-fibres in the vascular system do not lie in close apposition to each other, but are separated by interstitial spaces; each fibre also contains only one nucleus.—Dr. van der Gehnchten, of Holland, gave a short abstract of his observations on the minute structure of striated muscles in Vertebrata and Arthropoda. He described the appearance of the muscles in the fresh conditions, after the coagulation of the myosin and after the solution of the amorphous proteid, and illustrated his statements by drawings. According to these researches the muscle-fibre of the Vertebrata consists of a network of doubly-refractive filaments, whose meshes are filled with the semi-fluid plasmatic substance. In Arthropoda the structure differs according as the muscle is taken from the wings or the legs; when taken from the latter the structure is extremely similar to that in the Vertebrata. In the discussion which followed, Dr. Benda pointed out that being engaged for years in studying the structure of striated muscle he had often obtained preparations similar in appearance to those of Dr. van der Gehnchten, but his interpretation of these appearances was very different. He pointed out, moreover, that he had often observed transitional forms between the muscles of the leg and wing in Arthropoda and those of Vertebrata. Without entering into any details, Dr. Benda gave it as his opinion that the network in a striated muscle-fibre must not be regarded as contractile, but as a connective-tissue interstitial substance, in whose interspaces the really contractile muscle fibrillæ lie.

IN the report of the meeting of the Physical Society in NATURE of June 21, p. 192, for "Dr. Lummer" (line 37 from the bottom) read "Prof. von Helmholtz."

CONTENTS.

THURSDAY, JULY 19, 1888.

THE CHOICE OF A CHEMIST TO THE NAVY.

SIR HENRY ROSCOE'S watchful regard of the true interests of science was evidenced by his recent question in the House to the First Lord of the Admiralty, whether, in consequence of the resignation of Dr. Debus of the Professorship of Chemistry in the Royal Naval School at Greenwich, it was proposed to reduce the status of this post to a lectureship; and if so, whether he would take into consideration the inexpediency of this step being taken, in view of the importance to naval officers of a knowledge of this science, and of the necessity that in the Government Naval School the post in question should be filled by a gentleman of the highest possible scientific position and attainments.

Lord G. Hamilton is reported to have replied that the resignation of Dr. Debus, Professor of Chemistry at the Royal Naval College, had only just been received by the Admiralty, and therefore it would be premature to make any statement as to the manner in which it may be thought desirable to fill the vacancy so caused. The policy of the Admiralty was always to inquire into the circumstances of any appointment of this kind that may fall vacant, with the view of adjusting the salary to the requirements of the day.

It must be obvious that this statement savours most strongly of officialism, and that it affords no information whatever with regard to the views and intentions of the Admiralty. We have already clearly indicated what are the requirements of the day, and Sir Henry Roscoe has given emphasis to our views; but it is more than probable that unless attention be again directed to the importance of the issues involved in the appointment of a chemist to the Navy the course of action indicated in our previous article as likely to be followed will inevitably be adopted.

We therefore without hesitation again urge that in a case of this kind only one course can be adopted with safety by the Admiralty, if the interests of the nation are to be considered—that course is to engage the services of the best man available. No candidate's claims should be considered unless it can be shown that he is a trained chemist, and has been actively engaged in the pursuit of new knowledge; and unless it appear probable that he is enthusiastic and single-minded enough to continue to interest himself in research work and to lead his senior pupils to engage in research. We are fully aware that in imposing this standard we are demanding higher qualifications than many may consider necessary; that some may even think that nothing more is required at Greenwich than one who will teach young midshipmen the elements of chemistry and simple analysis fairly well; but to this we demur most emphatically, believing it to be incontestable that the science of chemistry may minister directly and indirectly in so many ways to the wants of our Navy that it is essential to give it the highest possible footing in the course of study at a naval college.

In the recently published life of W. E. Forster, a fragment of conversation at a dinner party preserved by Mrs. Forster is recorded which will be aptly quoted here. "Mr. —— said that —— was always going about asking people what was the ideal towards which they were working, and there was a laugh at the notion. But my husband did not join in it, saying that, for his part, if he was not constantly thinking of the ideal which he was working up to, he should not be able to get on at all." We venture to think that the infertility of British chemists and the inferior position which chemistry holds in this country, especially at our two great universities, as well as our failure to excel in those industries in which chemistry plays an important part, are due to the absence of an ideal among our chemists generally in any way approaching to that which has long obtained in Germany, where no higher grade appointment can be bestowed except on a man who is master of his subject, and not a past-master even but an active worker; and it is the absence of any such ideal which in cases like the present renders it possible for the authorities to entertain the suggestion of reducing the status of the post at Greenwich.

We believe that a master chemist is required at Greenwich for a variety of reasons. Firstly, as a matter of national honour; secondly, because, as we have already said, the subject must be taught technically, *i.e.* with direct reference to the knowledge and requirements of the students; thirdly, because the students are not only young beginners, but are of all ages, including many men of ripe experience, and it is scarcely necessary to remark that no one who is not a thorough chemist can possibly gain the sympathies of this latter class; and, lastly, because no one who is not himself actively engaged in research will remain *au courant* with the progress of knowledge, and will be able to select and incorporate into his teaching important new facts, thus avoiding the otherwise inevitable tendency to teach in a stereotyped and bookish fashion from year to year.

The proper man being found, he should be told at the outset that it is expected that when engaged in investigation he will devote his attention primarily to problems of importance in the Navy; a short intercourse with men versed in naval affairs and requirements would soon furnish an active-minded chemist with more than sufficient subject-matter meriting attentive study. It is more than probable that if a good example were set, and a spirit of enthusiasm kindled among the students, officers who had been led to take a real interest in chemistry would be willing, in the intervals of enforced inactivity when they were not on service, to devote themselves to research; and if but moderate encouragement were given to such men, we can conceive that Greenwich at no distant date might become an important school of naval research.

Unfortunately it is only too obvious that the public are slow to heed the repeated warnings of experts that our competitors in commerce are outrunning us largely because of their readiness to avail themselves of the aid which science can afford to industry. The evidence that foreign Governments are more anxious than is ours to make every possible use of science in the service of the Army and Navy is also growing daily; but we are confident that in the present instance the danger of the retrograde action which appears to have been contemplated having been pointed out, the naval authorities will not allow themselves to be guided by shortsighted advisers, and will no longer countenance any change which does not enhance their opportunities of receiving aid from so all-important a branch of science as chemistry.

NEW WORKS ON LEPIDOPTERA.

South African Butterflies: a Monograph of the Extra-Tropical Species. By Rowland Trimen, F.R.S., &c., assisted by James Henry Bowker, F.Z.S. Vols. I. and II. Royal 8vo. (London: Trübner and Co., 1887.)

Descriptions of New Indian Lepidopterous Insects from the Collection of the late Mr. W. S. Atkinson, M.A. Part III. Heterocera (continued). By Frederick Moore, F.L.S., &c. 4to. (Calcutta: Published by the Asiatic Society of Bengal, 1888.)

MORE than twenty-one years have elapsed since Mr. Trimen finished the publication of his "Rhopalocera Africæ Australis." During the whole of this time he has kept the subject of South African butterflies steadily in view, and the number of additional species discovered in South Africa is so large that he has chosen a new title for his book rather than call it a second edition of the old one.

Between 1866 and the present time the number of species of butterflies known to inhabit South Africa has swollen from 222 to 380, and instead of a small octavo volume we have now before us two out of three royal octavo volumes of goodly dimensions. This progress in the study of a favourite group of insects in South Africa probably represents a similar progress in the knowledge of the butterflies of the world, for nearly everywhere it has been increased by rapid strides.

Mr. Trimen has had the advantage of living in the country the butterflies of which he describes, and he has been in close correspondence with numerous enthusiastic helpers, foremost amongst whom is Colonel J. H. Bowker, whose name appears on the title-page as Mr. Trimen's coadjutor.

The earlier chapters of the work are devoted to general subjects relating to insects and leading up to the special subject in view. In all this portion Mr. Trimen has exercised admirable judgment, giving the leading points in concise but clear language. The classification adopted is that of Mr. H. W. Bates, which has now stood the test of many years' practical working, hardly any important alteration having been made in its main features since it was published. Still, much remains to be done before some of the great families, such as the Lycænidæ and Hesperidæ, and sub-families, such as Satyrinæ and Nymphalinæ, can be reduced to order.

As is well known, the front pair of legs in the imago provides one of the most important characters for determining the families of butterflies. Their examination affords a most interesting study. Owing to improved methods of preparing these limbs, whereby their scaly clothing is either destroyed or rendered invisible, they can be conveniently arranged for microscopic examination. The full extent to which they are atrophied is thus clearly revealed. The front legs of the males in the members of some families have their tarsal joints either more or less fused together or reduced to a single atrophied joint; but the variation in the extent to which this takes place is great. It sometimes also happens that when a number of individuals are examined, one will be found in which rudimentary spurs appear, and even unsymmetrically and attached to one tarsus only and not the other of the same insect. In some cases recently examined, males in the Erycinidæ have been found with the front legs furnished with the full complement of joints and with claws. The like occurs in the Lycænidæ both in America and in South Africa. Such cases, however, are exceptional, and though they break down to some extent the universal application of these characters to the discrimination of families, discrepancies are only to be expected, and the wonder is there are so few of them. Mr. Trimen appears to have studied this part of his subject with care, but a closer examination than is usually made will repay the labour of arranging the preparations. Though the variation in the relative lengths of the femur, tibia, and tarsus have been compared, the coxa has seldom been taken into consideration. Yet it, too, furnishes useful points for distinguishing forms, and in the case of the Erycinidæ the prolongation of this joint in the male front leg beyond its junction with the trochanter is diagnostic of the family. Mr. Trimen has not made any use in his classification of the varied structures presented by the secondary sexual characters of the terminal segments of the body; but there can be little doubt that, as improved methods of preparation are discovered, these characters will be found very useful in determining the relationship of species if not of genera.

The limits of the fauna treated of, as the title of the book states, extend from the Tropic of Capricorn southwards to the Cape of Good Hope. This district forms a sub-region of the great African or Ethiopian region. Its distinguishing characteristics are mainly negative, only six out of the sixty-nine genera not being found elsewhere, though 195 out of 380 of the species are peculiar. Whether the northern limit of this section of the African fauna really lies along the tropic remains to be seen, as our knowledge of the butterfly fauna north of this line is very meagre: of the interior we know nothing, and of the coasts not much. Regarding the internal distribution of the species, it would appear that the western and central portions, as well as that in the neighbourhood of the Cape, are poor in species. During a residence of over twenty-five years, Mr. Trimen has succeeded in capturing only forty-seven species within a radius of twelve miles from Cape Town. In the eastern districts the fauna is richer: Natal produces 206 species, and in the neighbourhood of Delagoa Bay many additional species occur. Each species is very fully described in this work, and many useful notes are added whereby the allied forms may be discriminated. Their history and range are also given with great precision. The larvæ and pupæ of many species are described, and this feature is a very acceptable addition, as most works on exotic Lepidoptera are silent on the subject.

The portion of the introduction that will be read with the greatest interest is that which relates to protection, resemblances, mimicry, &c. (pp. 32-40). A concise summary of the best work on this subject is given; and the instances furnished by the African butterfly fauna are described more in detail. Some years ago Mr. Trimen brought forward some very interesting cases of mimetic resemblances in butterflies, the most important being that in which *Papilio merope* is involved. He was able to prove that, wherever it is found, the females of this species take the pattern of a *Danais*, and though the males hardly vary over a very wide area, the female varies with the *Danais* in each district except in

Madagascar and Abyssinia, where females and males are alike.

The plates, on which a selection of the less known species are depicted, are chromolithographs, and are rather uneven in quality, as is usually the case in drawings of butterflies by this process. Some of the figures are admirable, while others, such as the Lycænidæ, are not at all satisfactory. Notwithstanding this defect, we can safely say that Mr. Trimen's "South African Butterflies" is the best-planned and best-executed work of its kind that has yet appeared. It cannot fail to promote an accurate study of the Lepidoptera of the country of which it treats; and it may serve as a model for entomologists to follow when writing of the butterflies in other portions of the world.

Mr. F. Moore's book on new Indian Lepidoptera, the third and concluding part of which is before us, is a work of a very different character from Mr. Trimen's, and consists of descriptions of new species from the collection of the late Mr. W. S. Atkinson. Mr. Moore has long been engaged on work of this kind, and every year issues scores of descriptions of Lepidoptera, chiefly Heterocera, of India. His former position as Assistant Curator to the Indian Museum placed him in communication with a number of correspondents, who have helped him to gather together probably the most important collection of Indian Lepidoptera in existence. Without such a collection no work like the present could be undertaken. We confess, however, to a feeling of despair as to the future of the subject treated of when we glance at the descriptions before us. They are descriptions of the barest kind, scarcely relieved by a few comparisons, and with hardly a note to break the tedious monotony of the frequent repetition of the same characters over and over again. Whether future workers will be able to determine species by them without reference to the types is more than we can say, but we do not envy them the task of trying the experiment. And here we note with regret that the types of these species are not to be found in our National Collection, but in the possession of Dr. Staudinger, of Dresden, and some of them in Mr. Moore's own cabinets. This might have been otherwise had more interest been shown by our home authorities in the productions of our great dependency.

On the title-page of this part it is stated that members of the families Pyralidæ, Crambidæ, Geometridæ, Tortricidæ, Tineidæ are treated of, but in the body of the work new species are referred to no less than twenty-three other families of Heterocera. In the present state of the classification of Heterocera such an oversight is hardly to be wondered at. No serious attempt has been made for many years to place the classification of the moths on a sound and definite basis. The old systems are to a great extent obsolete, and the more recent attempts to modify them, by their halting and spasmodic character, have increased rather than lessened the confusion.

Mr. Moore has introduced a number of new generic names into this work, but he seldom gives any clue to the relationship of the proposed new genus. On p. 283 he commences descriptions of some "additional species" by introducing five new generic names for sections of the great genus *Papilio*. Whether this genus should be divided into many or left as a large aggregate of species is a disputed point, but we have no hesitation in condemning the plan here adopted of thrusting these names upon us in this piecemeal fashion. To anyone who will give the whole subject a careful examination and work out the diagnostic characters of the groups of this wonderful genus we are prepared to give a patient and respectful hearing; but to name sections here and there, with brief descriptions which are anything but diagnostic, is a practice to be deprecated.

Three coloured plates accompany this part, on which eighty-seven species are depicted. These are carefully drawn and nicely coloured, and form a substantial addition to the book.

We note that the first sheet of this part bears the date of September 5, 1887, but the title-page that of 1888. The meaning of this is not obvious, as the former is valueless in face of the later date of the title-page and wrapper.

FACTORS IN LIFE.

Factors in Life. By H. G. Seeley, F.R.S. "People's Library Series." (London: Society for Promoting Christian Knowledge, 1888.)

THE book before us is one of the useful series of household guide books, published by the Society for Promoting Christian Knowledge and intended to instruct the people in some of the more important laws of health. There are so many guide books on this subject at the present time that Prof. Seeley has, we feel sure, found it a difficulty of no slight kind to put before his readers the material he had in hand, so as to feel that he was supplying anything that by its novelty could be considered acceptable. Happily the enormous importance of his theme has come to his aid, and has enabled him to bring forth an essay which makes up in earnestness whatever it may, by very necessity, want in originality; for health is like truth—it can never be confirmed enough, nor have too many able expositors.

The factors in life treated of by our author are health, food, and education. Health he defines, very tersely, as "the condition of life in which the body produces more energy than is lost in performing our work"; and then he proceeds to indicate the various methods, habits, and practices by which it can be secured by the individual and by the community at large. With much prudence the Professor dwells on the obstacles that lie in the way of health from the expense that attends their application. He illustrates this uncommonly well in regard to cleanliness. "The difficulty," he says, "of securing the universal practice of the habit is chiefly a matter of expense. There are few pleasures more costly than perfect cleanliness, since it implies labour in every detail." Here, too, he enforces what all practical sanitarians have foreseen, that such labour can never be satisfactory unless the woman of the house, the wife, can direct and take part in it, "because servants can in no other way become of the same flesh and blood as their employers. Personal cleanliness to be of any value must extend to all members of a household. It is as important for the servants as for the mistress, for they are often exposed to greater chances of infection, and have greater capacity for diffusing disease. If the cook and the kitchen are not scrupulously clean, the health of the household suffer with every touch given to food, and many an obscure derangement of health which baffles medical skill is due to this poison of dirt." Touching the question of national cleanliness, we are very glad to find Prof. Seeley spotting the greatest of all political evils of a social kind—the evil of allowing a monopoly to companies for the supply of fresh water to the community. "The wisdom of the State," he affirms, "never permitted any greater obstacle to come between the people and their health than the monopoly of water companies who make water an article of trade;" from which saying we only dissent in regard to one word—the word wisdom, for which the truer word folly ought, we think, to be substituted.

Prof. Seeley takes a decisive view of the duties of the members of the profession of medicine, to whom he would apply the drastic reformation inaugurated by that heathen Chinee, who makes the doctor earn his fees not by treating the man that is sick, but by keeping the man that is whole always free from sickness. The doctor, according to this prescription, would keep up the health of the household by contract, through which plan there would be no necessity for sick-hospitals, sick-beds, or any other of the extensive and costly methods now in use for keeping up the cure of disease. The whole art of medicine would be an art of prevention; and cure, now the almost sole object of the highest skill in medicine, would be quite subordinate to prevention. But where then would poor medical science be landed? Every man would be his own general practitioner, every housewife would be a physician, every old woman who had gained most experience from observation of preventive measures would be a consulting physician, and there would be nothing to cure. Fie on you! learned, if not jealous, Professor, for suggesting such a heartless disintegration of the great and noble sciences of pathology and therapeutics. The next time we meet you we will not speak to you unless you publicly recant such brazen heresy, and repent in dust and ashes. Seriously, the idea of such a change is not far off, and indeed has, to some extent, commenced amongst the more advanced members of the educated community. It is an idea that will spread far and wide, and in half a century or so may be the fashion of the time.

On the topic of food our author is very explicit, and is strong in his recommendations to feeders generally that they should distinguish carefully between foods that are *bonâ fide* foods, and those which are merely stimulants. Tea and drinks of its class owe their popularity to their power of arresting waste or nervous exhaustion, and this constitutes their superiority over alcoholic drinks. Neither, perhaps, is food in the popular sense of the term. "Wine and its allies give a fillip to the nervous system, which enables exceptional work to be done at the price of increased nervous exhaustion, and draw a bill on the strength which must be met at a short date: while tea and its allies enable increased work to be done by making the dormant strength available, and discount, on favourable terms, the bills we hold on nervous energy." This is sound and plain teaching, told in a concise form, that deserves to be retold by all who have the advantage of learning from the volume before us.

We are glad to see that Prof. Seeley inclines calmly and judiciously to the advocacy of a more distinctive national leaning towards vegetable products as foods. He sees that the ease with which animal foods can be prepared for the table is greatly to the advantage of their popularity, until a better system of cookery is established throughout the land, in which vegetable foods shall play a more distinguished part than they have ever yet played in this country up to the present date. "The sum," he tells us, "that is annually spent on animal food in this country is more than £114,000,000, or upwards of a ninth of the national income; while the sum spent on bread, potatoes, and vegetables combined is £127,000,000. By a reformed diet it is probable that a substantial saving of about £30,000,000 a year might be made in the cost of nitrogenous food alone, without any serious change in national habits, and with advantage in every way."

Turning lastly to the essay on education as a factor in life, we find excellent rules for combining education with health, and both with good morals. "Education begins earliest in childhood, ends only in death, and survives death itself in its effects on after time." In fact, "Nature has appointed no period for education." These are some of the wise and prudent sayings which the author places before his readers, with many others on which we have not space to dwell. But it would not be just to conclude without directing attention to the *summum bonum* of educational efforts which, in his last pages, Prof. Seeley impresses on his countrymen. He deals here with the subject of education on its religious side. The religious feeling is, he contends, partly an inherited character of the race, and partly the product of education. But, unless it permeates and saturates life so that every act and endeavour of existence has a basis which unites them into one sustained movement onward towards higher things, he should not express what he conceives the religious side of the education of life should be. The sciences are the sisters of religion, in that they unfold something of the laws by which the universe is governed and by which the life of man is directed. "They are thus far the stepping-stones of faith. And those who have learned that health is the reward of moral discipline, that mental vigour may be augmented by the wise or moral use of food, and that education is the systematic exercise of moral responsibility in any or all the affairs of life, may find that in the practice and the pursuit of the truths of science they are conscious of a religious education which is a light to their feet." The words are true. The words are a true gospel—a gospel new and true and ever-extending; and we congratulate the religious Society which has had the courage to publish them, as heartily as we congratulate the author who has had the good sense and moral faith to send them forth for publication.

THE LANDSLIP AT ZUG.

Die Catastrophe von Zug, 5 *Juli*, 1887. (Zürich: Hofer und Burger, 1888.)

AN account of this catastrophe, written by Prof. Bonney, who visited the scene of ruin, has already appeared in the pages of NATURE (vol. xxxvi. p. 389). The present volume, compiled from official documents, gives a fuller history and more minute details of the results of the slip than were at that time accessible. It mainly consists of an elaborate report, written by Dr. A. Heim, the well-known Professor of Geology at Zürich, "Ober-ingenieur" R. Moser, and Dr. A. Burkli-Ziegler, to which are appended brief accounts of the incidents of the catastrophe, and of that which occurred in 1435, and lastly, a note on the disposal of the fund raised for the benefit of the sufferers. Plans and sections (extracted from the series which was attached to the above report) accompany the book, and indicate very clearly not only the amount of the mischief done, but also its cause, which, as already stated in these pages, is the existence of a deep deposit of silt beneath the superficial gravelly soil. The latter is but a very few feet thick, and suffices for the foundation of the less important buildings; the former constitutes the shelving bed of the lake to a depth of more than 100 feet. Borings made at various stations on the land, not far from the lake margin, have shown that this material remains incoherent to nearly the above depth, after which it becomes stronger. Hence there is always a danger of the underlying silt being squeezed outwards into and upon the bed of the lake, and the plans and sections furnished with the present volume show precisely how the accident occurred. There appear to have been some premonitory indications of the coming mishap, in addition to the subsidence in the new pier wall, which had already excited alarm. The inhabitants of certain houses, which afterwards fell, had observed sundry small displacements, which were especially shown by the jamming of doors and windows; cracking noises also had once or twice been heard. But the actual catastrophe was very sudden. About 3.20 p.m. the end of the quay wall, which had been completed up to a sort of little bastion, began to crack and sink. A quarter of an hour later came the first great slip, which caused the loss of seven lives. Except for some minor slips, there was then a pause for rather more than three hours, and then at 6.50 p.m. the second and greater slip occurred. A graphic account is given of the terror caused by this second catastrophe, which caused the loss of four more lives. A third, but comparatively unimportant, slip occurred at 10.15 p.m.

From the plan and sections it is evident that the second slip affected the larger area, both of the land and of the lake bed. Each slip forced the loose silt horizontally outwards, so as to form a delta-like deposit on the lake floor, thus diminishing the depth of the water sometimes by about 4 or 5 yards. At the first slip a triangular piece of ground, measuring about 80 yards along the shore, and some 40 yards to its apex inland, was destroyed, and the "delta" produced by this, which in outline resembles a rather stout pear, is about 250 yards across the wider part, and apparently extends to about 450 yards from the shore. By the second slip not only a much larger piece of the land (with a rudely oblong boundary) was removed, but the lake bed opposite to it, for a distance of 220 yards, appears to have slipped, so as to form a kind of broad trench, resulting in an interval of deeper water some 50 yards wide. The material thus removed was deposited over the deeper part of the lake bed, covering a space not quite so wide as that occupied by the former "delta," but much more than double the length, for its end is placed 1020 metres from the shore, at a depth of 44 metres.

These elaborate maps and sections, with the results of investigations (by means of borings) into the nature of the lake bed, the level of the ground water, &c., give a high value to this publication, which may be commended to the notice of architects and engineers, as well as to those interested in the history of Switzerland.

OUR BOOK SHELF.

Turbans and Tails; or, Sketches in the Unromatic East. By Alfred J. Bamford. (London: Sampson Low, 1888.)

THE author of this book does not claim to have anything very new or striking to tell his readers. He has seen a good deal of India and China, and is content with reproducing, in a popular way, the impressions made upon him during his not very exciting sojourn in those countries. He has little to say about "the mild Hindu" or "the man of Han" that tends to make us think more highly of either. Mr. Bamford, like many English travellers, is apt to be impressed by the bad rather than by the good aspects of unfamiliar types of character; and some of his sweeping judgments would no doubt have been considerably modified if, in estimating the intellectual and moral qualities of Orientals, he had remembered more frequently and vividly than he has actually done, that thought and conduct in the East and West cannot always be fairly or wisely measured by the same standards. The book, however, has the merit of being written in a lively style, and the author's judgments, whether sound or unsound, invariably result from his own observation and reflection. Here is one of a good many suggestive anecdotes which brighten his pages: "Of what caste are you?" asked an Englishman of a native of India. "Oh," replied the native, "I'm a Christian—I take brandy shrab, and get drunk like you."

The Photographer's Note-book. By Sir David Salomons, Bart., M.A. (London: Marion and Co., 1888.)

BOTH amateur and professional photographers, and especially those who travel and take a great number of photographs per day, will find this little book very handy and useful, as it is of a very convenient size and contains enough space for inserting the particulars, such as number of stop, rapidity of shutter, remarks on the light, &c., of each of fifty-one dozen plates.

Formulæ for enlargement and depth of focus and rules for exposure are added, followed by a table, calculated by Messrs. Marion, of the correct quantities to be taken from 10 per cent. solutions to make up developers for all the best known plates. The book concludes with various tables, such as area enlarging, enlarging by linear dimensions, and equivalent focal lengths of lenses of different sizes and makers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Cloud Electric Potential."

I DESIRE to draw the attention, more particularly of your electrical readers, to the following paragraph on p. 651 of the eighth edition (1884) of Deschanel's "Natural Philosophy," part iii., which appears distinctly at variance with the theory o thunderstorms as explained in Prof. Silvanus Thompson's "Elementary Lessons," and similar elementary treatises:—

"The coalescence of small drops to form large ones, though it increases the electrical density on the surfaces of the drops does not increase the total quantity of electricity, and *therefore cannot directly influence the observed potential.*"

Surely this entirely omits the fact that the capacity of a sphere is equal to its radius, and thus in the case of eight equal spheres coalescing into one (which is taken by Prof. Thompson), not merely would the density be doubled, but the potential of the *same quantity* would be increased *four* times.

In the well-known case given by Prof. Tait for the formation of a raindrop the potential of the same quantity might be increased fifty million times.

The source of the energy which is the cause of the increased potential in this case, is probably the molecular force of cohesion released during the act of condensation and union, the cohesion and the electricity being oppositely placed, so that while the former is running down hill (as it were) the latter is obliged to run up; the top of the hill answering to the critical moment for disruptive discharge.

In view of these facts, it seems to me that if the above sentence is not altogether erroneous, it is certainly ambiguous, and liable to breed false notions in the mind of the unreflecting and too credulous student. E. DOUGLAS ARCHIBALD.

Transparency of the Atmosphere.

IT may be, I think, desirable to correct an error which has crept into all the accounts of the extraordinary transparency of the atmosphere observed here last week. It occurred on Sunday, the 8th, and not on Monday, the 9th inst. I can confirm the several details as to the objects visible to the unassisted eye. But in one respect this effect was surpassed on August 20, 1887, when the double flash of the Dunkirk light, distant from this place about forty-five miles, was visible for several hours. This light could not be seen here on the 8th inst.

Pavilion Hotel, Folkestone, July 16. J. PARNELL.

Preserving the Colour of Flowers.

IN response to the inquiry of "A. W.," perhaps you will allow me to say that many years ago I met with Mdlle. d'Angeville, the first lady to ascend Mont Blanc. She possessed the largest and best preserved collection of Alpine flowers I have ever seen, and she assured me she never used anything but cotton-wool in her press, changing it, of course, frequently. Her gentians, pedicularias, and other delicate plants were perfect in colour; and having tried her plan myself, although with less care, and therefore with less success, I still have Alpine flowers which have retained their colour for twenty years.

54 Doughty Street, July 17. A. W. BUCKLAND.

Distribution of Animals and Plants by Ocean Currents.

IN connection with Miss Buckland's letter on this subject it may be interesting to note that, during a visit to Orotava, Teneriffe, in April 1887 (about the time mentioned by your correspondent), I observed and gathered a quantity of pumice-stone upon the seashore, the high tide mark being literally strewed with it. It seemed probable that it had been deposited there some weeks or possibly months previously, as, had there been any quantity floating about in the sea, I should have noticed it, being engaged at the time tow-netting in the neighbourhood and in the adjacent Canary Islands. There was no evidence of vegetable debris having accompanied the pumice, nor did I notice any pieces with barnacles attached.

Liverpool, July 13. ISAAC C. THOMPSON.

A Curious Resemblance

WHILST walking by the sea on the cliffs last Sunday, I perceived at a distance of about 1500 yards a flight of nearly forty ducks, travelling at a good pace 2 or 3 feet above the level of the water. To me they appeared exactly what the so-called "sea-serpent" would, eight or ten of the birds flying close together and forming the head, whilst the rest trailed behind and formed the body and tail. At intervals they disappeared. This was caused, I think, by the birds changing their course and flying either directly away or towards me; the former, I believe, in my case.

Some time afterwards I saw two other flights, and these resembled the first exactly, those with me also being surprised at their "snake"-like appearance. W. J. LOCKYER.

Thanet, July 16.

The "Sky-coloured Clouds."

THERE was a very bright display of these clouds last night. I could not perceive anything of them up to 10 p.m., though the sky was clear, but by 10.18 they had become conspicuous, and were brightest, so far as I observed, near midnight.

I have seen very little account in any English paper of the visibility of these clouds beyond England, nor do I know whether they have been seen elsewhere than in Northern Europe. Has there been anything published on these points in English?

Neither have I seen any reference to the extensive observations of Herr O. Jesse at Steglitz, with his suggestions to observers. He considers it very important that this unusually favourable opportunity should be utilized for learning the motions of currents at great heights in the atmosphere. He suggests that photographs taken simultaneously from two places at a distance of say 20 kilomètres would be useful for ascertaining the height of the clouds; but for this purpose the necessity arises of being able to calculate very accurately the azimuths and altitudes of different points in the photograph. Their height can likewise be determined, though less accurately, by observations of the limit of sunshine upon them. Herr Jesse proposes another way also, viz. by throwing an intense beam of electric light on the clouds; but I should doubt the practicability of this.

The direction and rate of motion could be best made out, he says, by the use of a cloud-mirror. The changes that take place in the forms of the clouds before they have moved far make it difficult to ascertain their motion accurately.

Herr Jesse further thinks the intensity of the light of the clouds in different positions should be determined; also that the sky should be examined in the day-time with a polariscope and photometer in the hope that the presence of the matter of the clouds, then invisible to the eye, might be revealed.

Sunderland, July 13. T. W. BACKHOUSE.

An Unusual Rainbow.

SINGULARLY enough I can record the appearance of a rainbow after sunset similar to that described by Mr. S. A. Hill (NATURE, March 15, vol. xxxvii., p. 464). I was not aware there was anything unusual in it until I read Mr. Andrew's communication, or would have written to you about it. I do not remember on what day I saw the rainbow, but it was about the date of that observed by Mr. Andrew. I called my wife's attention to it, and attributed it to the brilliant glow of the sunset tints. It had a secondary bow, and Mont Kogie as a dark background. E. L. LAYARD.

British Consulate, Noumea, May 15.

TIMBER, AND SOME OF ITS DISEASES.[1]

IX.

IF the leaves are stripped from a timber-tree early in the summer, or during their young conditions in the spring, the layer of wood produced in the current year—and probably even that formed next year—will be poor and thin. This is simply a fact of observation, and does not depend on what agent deprives the tree of its leaves. Those oaks which suffered so greatly from the ravages of certain tiny caterpillars this last summer (1887)—many of them having all their leaves eaten away before July—will have recorded the disaster by a thin annual ring of wood: it is true the more vigorous trees produced (at the expense of what stores of food materials remained over) a second crop of leaves in August, and so no doubt the zone of wood will prove to be a thin double one, but it is at the expense of next year's buds.

[1] Continued from p. 170.

Now there are very many foes which injure the leaves of our timber-trees, and I wish to show, as clearly as possible in a short article, how it comes about that injury to the leaves means injury to the timber. The sum total of the matter is that the substances which are to be sent down to the cambium, and converted through its agency into wood, are produced in the cells of the leaves: consequently, from our point of view, when an insect or a fungus consumes the substance of the leaves, it consumes timber in prospective. Similarly, when the leaves are removed from a tree by any agent whatever, the latter is robbed in advance of timber. A leaf, generally speaking, is an extended, flattened portion of a branch, covered by a continuation of the epidermis of the branch, and containing a continuation of its other tissues—the vascular bundles of the branch being continued as the venation, and the cellular cortex reappearing as the green soft tissue of the leaf. The epidermis of the leaf is so pierced at hundreds or thousands of nearly equi-distant points, that gases can enter into or escape from all its tissues: at these points are the so-called *stomata*, each stoma being a little apparatus which can open and close according to circumstances.
